Abstract. The response function identification method introduced in the first part of this study is applied here to investigate the land carbon cycle in the Max Planck Institute for Meteorology Earth System Model. We identify from standard C4MIP 1% experiments the linear response functions that generalize the land carbon sensitivities $\beta$ and $\gamma$. The identification of these generalized sensitivities is shown to be robust by demonstrating their predictive power when applied to experiments not used for their identification. The linear regime for which the generalized framework is valid is estimated, and approaches to improve the quality of the results are proposed. For the generalized $\gamma$ sensitivity, the response is found to be linear for temperature perturbations until at least 6 K. When this sensitivity is identified from a 2xCO$_2$ experiment instead of the 1% experiment, its predictive power improves, indicating an enhancement in the quality of the identification. For the generalized $\beta$ sensitivity, the linear regime is found to extend up to CO$_2$ perturbations of 100 ppm. We find that nonlinearities in the $\beta$ response arise mainly from the nonlinear relationship between net primary production and CO$_2$. By taking as forcing the resulting net primary production instead of CO$_2$, the response is approximately linear until CO$_2$ perturbations of about 850 ppm. Taking net primary production as forcing also substantially improves the spectral resolution of the generalized $\beta$ sensitivity. For the best recovery of this sensitivity, we find a spectrum of internal timescales with two peaks, at 4 and 100 years. Robustness of this result is demonstrated by two independent tests. We find that the two-peak spectrum can be explained by the different characteristic timescales of functionally different elements of the land carbon cycle. The peak at 4 years results from the collective response of carbon pools whose dynamics is governed by fast processes, namely pools representing living vegetation tissues (leaves, fine roots, sugars, and starches) and associated litter. The peak at 100 years results from the collective response of pools whose dynamics is determined by slow processes, namely the pools that represent the wood in stem and coarse roots, the associated litter, and the soil carbon (humus). Analysis of the response functions that characterize these two groups of pools shows that the pools with fast dynamics dominate the land carbon response only for times below 2 years. For times above 25 years the response is completely determined by the pools with slow dynamics. From 100 years onwards only the humus pool contributes to the land carbon response.

1 Introduction

In Part 1 of this study (Torres Mendonca et al., 2021a) we developed a method to identify linear response functions from arbitrary perturbation experiments. The RFI method (response function identification method) was tested by means of artificial toy model simulations. Here, we demonstrate the applicability of our method to a practical problem: we in-
vestigate the dynamics of the land carbon cycle in the Max Planck Institute for Meteorology Earth System Model (MPI-ESM; see Appendix A). In particular, we show how our RFI method provides insight into two aspects of central relevance to carbon cycle research: the sensitivity of the land carbon cycle to changes in atmospheric CO₂ and its distribution of internal timescales.

The global carbon cycle plays a critical role in mitigating climatic effects from CO₂ emissions. According to the yearly published Global Carbon Budget (Friedlingstein et al., 2020), the ocean and land components of this cycle have taken up about half of the anthropogenic CO₂ emitted from pre-industrial times to 2019. Despite its relevance to climate, the dynamics of the carbon cycle is still poorly understood (Ilyina and Friedlingstein, 2016). Improving our understanding of this dynamics, in particular in response to CO₂ perturbations, is therefore one of the major challenges of climate research (Marotzke et al., 2017).

A tool long employed to investigate the carbon cycle dynamics are linear response functions. Such functions have been used to predict atmospheric CO₂ from emissions (Bolin et al., 1981; Siegenthaler and Oeschger, 1978; Oeschger and Heimann, 1983; Maier-Reimer and Hasselmann, 1987; Enting, 1990; Joos et al., 1996; Joos and Bruno, 1996), land carbon storage from NPP (net primary production) (Bolin et al., 1981; Thompson and Randerson, 1999) and GPP (gross primary production) (Emanuel et al., 1981), and to disentangle the historical development of the land and ocean carbon sinks from ice core reconstructions of atmospheric 13C and 14CO₂ (Joos and Bruno, 1998). Linear response functions have also been employed to study the dependence of global warming on possible future CO₂ emissions and the associated GWP (global warming potential) (Caldeira and Kasting, 1993; Joos et al., 2013; Caldeira and Myhrvold, 2013; Ricke and Caldeira, 2014; Gasser et al., 2017).

However, a generally underexplored field in carbon and also climate research is that of internal timescales (see however Todd-Brown et al., 2013; Friend et al., 2014; Koven et al., 2015; He et al., 2016). Also here, linear response functions open an interesting perspective. To systematically investigate the interaction between climate and the carbon cycle, for more than a decade now internationally coordinated simulation exercises have been performed with several Earth system models within the Coupled Climate Carbon Cycle Model Intercomparison Project (C₄MIP; see Fung et al., 2000; Friedlingstein et al., 2006) that today belongs to the international Coupled Model Intercomparison Project (CMIP; see Taylor et al., 2012). With every round of CMIP, quite some effort is put into understanding how differences in simulation results from the participating Earth system models arise (see, e.g., Anav et al., 2013; Tebaldi et al., 2021; Arora et al., 2020). It is pretty clear that parts of the differences arise from different spectra of internal timescales. These differences show up, e.g., in the standard 4×CO₂ and 1 % experiments of the CMIP protocol that are explicitly designed to estimate equilibrium and transient climate sensitivity (Taylor et al., 2012; Eyring et al., 2016). However, such a characterization of the response of temperature to radiative forcing by only two numbers is rather incomplete: these numbers are the aggregated result of system responses at all its internal timescales together. Therefore, a more detailed insight into system behavior could be obtained from the knowledge of this spectrum of responses at different timescales. Such insight may be provided by considering the linear response function that generalizes climate sensitivity (e.g., Ragone et al., 2016). Further, this perspective to obtain from linear response functions information on internal timescales is not restricted to climate sensitivity, but also applies to other types of system characteristics like the airborne fraction (e.g., Le Quéré et al., 2009; Raupach, 2013), the TCRE (Transient Climate Response to Cumulated Emissions; see e.g., Ciais et al., 2013) and the β and γ sensitivities introduced by Friedlingstein et al. (2003) to characterize how land and ocean carbon react to rising CO₂ and rising temperatures. In the present study we explore the application of linear response functions to study β and γ. In particular, we focus on the β and γ values that characterize the land carbon cycle, whose response presents already for several C₄MIP rounds a large model spread (Friedlingstein et al., 2006; Arora et al., 2013, 2020).

When studying the land carbon response, the γ value quantifies the sensitivity of the land carbon cycle to the radiative effect of CO₂ acting via greenhouse warming, while the β value quantifies its sensitivity to the biogeochemical effect of CO₂ concentrations on photosynthetic carbon assimilation (Arora et al., 2013, 2020; Schwinger et al., 2014; Adloff et al., 2018). Mathematically, γ is defined as the ratio between changes in the land carbon caused by the radiative effect of CO₂ (ΔC^{rad}) and changes in temperature (ΔT) at a particular time:

\[ γ(t) = \frac{ΔC^{rad}(t)}{ΔT(t)}. \] (1)

β is defined as the ratio between changes in the land carbon caused by the biogeochemical effect of CO₂ (ΔC^{bge}) and changes in atmospheric CO₂ concentration (ΔC_{atm}) at a particular time:

\[ β(t) = \frac{ΔC^{bge}(t)}{ΔC_{atm}(t)}. \] (2)

However, although these two values give insight into the magnitude of the sensitivities, they cannot be seen as properties of the land carbon cycle alone. The reason is that γ and β quantify the sensitivity of land carbon to CO₂ perturbations only for a particular perturbation scenario, so that for different scenarios one may obtain different values (Gregory et al., 2009; Arora et al., 2013).

To quantify this sensitivity in a more systematic way and thereby gain deeper insight into the land carbon dynamics
one needs a more general formalism. For small changes in atmospheric CO₂ one can show that by accounting for the memory of the carbon cycle these values generalize to linear response functions, which turn out to be properties of the land carbon cycle itself (Rubino et al., 2016; Enting and Clisby, 2019, see also Appendix B). As a result, these linear response functions characterize the land carbon sensitivities for any perturbation scenario. For this reason these functions will here be called land carbon generalized sensitivities.

The essential step to investigate the carbon cycle dynamics within this general formalism is the identification of the generalized sensitivities. Typically, the γ and β values proposed by Friedlingstein et al. (2003) are obtained taking data from standardized C₄MIP simulation experiments where, starting from an equilibrium state, atmospheric CO₂ concentration is increased by 1% each year (e.g., Gregory et al., 2009; Arora et al., 2013, 2020; Schwinger et al., 2014; Adloff et al., 2018; Williams et al., 2019). Since data from such 1% experiments performed with C₄MIP models are readily available in international databases, one would be interested in identifying the generalized γ and β sensitivities as well from these experiments. However, methods in the literature to identify response functions from data require special perturbation experiments, and C₄MIP experiments were not tailored for this purpose. It is here that our RFI method is useful. Our method is designed to derive response functions from experiments driven by any arbitrary perturbation. Thus, in the present study we show that by this method one can robustly derive the land carbon generalized sensitivities for the MPI-ESM taking data from standard C₄MIP 1% experiments. To make sure the identified generalized sensitivities are indeed characteristics of the land carbon cycle in the MPI-ESM, we demonstrate their predictive power by applying them to predict the response of the model in several experiments that were not used for their identification. In preparation for future studies applying these generalized sensitivities to study the dynamics of the carbon climate system in C₄MIP models, we also investigate various ideas to improve the quality of the recovery of the response functions by using additional types of data routinely available in C₄MIP simulations or using log-transformed data to account at least partially for process-inmanent nonlinearities that hinder the usage of experiment data from larger levels of forcing.

Apart from giving a systematic quantification of the sensitivities, as hinted above linear response functions can be a powerful tool to gain insight into the internal dynamics of the carbon cycle. Because response functions fully characterize the linear response of a system, they contain information on its distribution of internal timescales, i.e., the weights with which characteristic timescales from internal processes contribute to the macroscopic response of the system. These weights may shed light into which are the most relevant processes to the response at different timescales. For our application to the land carbon, such information may give insight into the main processes influencing the model spread found in the C₄MIP results.

However, while several studies have tried to obtain the weights of different timescales in the carbon cycle by fitting response functions to a sum of a few exponents (Maier-Reimer and Hasselmann, 1987; Enting and Mansbridge, 1987; Enting, 1990; Joos et al., 1996, 2013; Pongratz et al., 2011; Colbourn et al., 2015; Lord et al., 2016), in principle it is not clear to what extent such results can be trusted, let alone interpreted. The reason is that finding these weights from data is a severely ill-posed problem that requires special methods to be dealt with (Istratov and Vyvenko, 1999). In contrast to the classical fitting procedures, by employing a regularization technique (Groetsch, 1984; Engl et al., 1996) combined with a novel estimation of the noise level in the data (see Part 1) our RFI method accounts for this ill-posedness. In addition, instead of assuming that the response functions result from only few timescales, the RFI method recovers a continuous spectrum of timescales, in agreement with what one would expect when studying the carbon cycle response (Forney and Rothman, 2012a). In the present work we show that, in contrast to results obtained with classical fitting procedures, spectra recovered by the RFI method may be reliable and even interpretable. For this purpose, we investigate a relatively detailed spectrum of timescales that arises from a high-quality recovery of the generalized β sensitivity. We examine (i) the robustness of the obtained spectrum and (ii) the explanation for its timescale structure.

An additional novelty introduced here is a simple procedure to estimate the linear regime of the response, i.e., the range of perturbation strengths for which the response of the system can be considered linear. As discussed in Part 1, the presence of traces of nonlinear responses in the data can severely deteriorate the recovery of the response function. Hence, to make sure that the data from which the response function is recovered contain no strong nonlinearities, one must be able to estimate the linear regime of the response.

Because the response functions will be derived from 1% experiments, we introduce a technique to estimate with the aid of additional simulations the linear regime from this type of experiment. By this technique the linear regime of the response of land carbon to changes in CO₂ and climate for the MPI-ESM will be estimated.

The outline of the paper is as follows. In the next section we introduce the methodology of the study including the RFI method, the C₄MIP experiments, and the technique to estimate the linear regime of the response from “percent” experiments. In Sects. 3 and 4 we identify and investigate the generalization of the γ and β sensitivities in the MPI-ESM. In Sect. 5 we investigate the detailed spectrum of timescales obtained for the generalized β sensitivity. In Sect. 6 the results are summarized and discussed.
2 Methodology

In this section we introduce the methodology employed throughout the study. We start by briefly introducing the RFI method (for a detailed description please refer to Part 1), the C\textsuperscript{4}MIP-type experiments considered here, and technical details for the identification of the generalized sensitivities. Then, we present our procedure to estimate the linear regime of the response from "percent" experiments.

2.1 RFI method and C\textsuperscript{4}MIP experiments

The RFI method identifies the response function $\chi(t)$ taking data from the response $Y(t)$ – in our example the global land carbon – and the perturbation $f(t)$ – atmospheric CO\textsubscript{2} or temperature (see below) – assuming the following relation (see Part 1):

$$\Delta Y(t) = \int_{0}^{t} \chi(t-s) \Delta f(s) ds + \eta(t).$$  \hspace{1cm} (3)

where $\eta(t)$ is a noise term. Here $\Delta Y(t)$ and $\Delta f(t)$ mean that we are taking only the change in the variables with respect to their equilibrium values from a control simulation. Following Forney and Rothman (2012a), the spectrum of internal timescales is obtained by assuming that the response function $\chi(t)$ can be represented by an overlay of exponential modes:

$$\chi(t) = \int_{-\infty}^{\infty} g(\tau) e^{-t/\tau} d\tau.$$ \hspace{1cm} (4)

To account for the large range of timescales in the carbon cycle (Ciais et al., 2013) it is useful to rewrite Eq. (4) in terms of $\log_{10} \tau$, so that

$$\chi(t) = \int_{-\infty}^{\infty} q(\tau) e^{-t/\log_{10} \tau} d\log_{10} \tau,$$

with $q(\tau) := \tau \ln(10) g(\tau).$ \hspace{1cm} (5)

The spectrum of timescales is then given by $q(\tau)$, which following the terminology in Part 1 we call simply spectrum. The problem is solved by discretizing Eqs. (3) and (5), prescribing a distribution of timescales $\tau$, taking the data on $\Delta Y(t)$ and $\Delta f(t)$, and solving a minimization procedure for the spectrum $q(\tau)$. The parameters to prescribe the distribution of timescales are taken identically to those chosen for the application to the toy model in Part 1. To treat the ill-posedness we employ Tikhonov–Phillips regularization (Phillips, 1962; Tikhonov, 1963) in a singular value decomposition (SVD) framework that gives the solution by the expansion (Hansen, 2010; Bertero, 1989)

$$q_{\lambda} = \sum_{i=0}^{M-1} f_{i}(\lambda) \frac{\mathbf{u}_{i} \bullet \Delta Y}{\sigma_{i}} v_{i},$$ \hspace{1cm} (6)

where $\bullet$ is the usual scalar product, $M$ is the number of timescales, $\mathbf{u}_{i}$ and $v_{i}$ are the singular vectors, $\sigma_{i}$ are the singular values, $\lambda$ is the regularization parameter, and $f_{i}(\lambda)$ are the filter functions

$$f_{i}(\lambda) = \frac{\sigma_{i}^{2}}{\sigma_{i}^{2} + \lambda}. \hspace{1cm} (7)$$

The regularization parameter $\lambda$ is determined by the discrepancy method (Morozov, 1966) with noise level estimated from a SVD analysis of the data combined with information from the control simulation. Once the spectrum $q_{\lambda}$ is found, the response function $\chi(t)$ follows from Eq. (5).

All linear response functions are identified by the RFI method taking data from C\textsuperscript{4}MIP-type experiments performed with the MPI-ESM. We focus on identifying the response functions from standard 1% experiments that are widely available in international databases. In addition, to examine the quality of the results, we also identify some response functions taking data from additional experiments. To investigate the robustness of the identified response functions, we employ them to predict the response of the MPI-ESM in several experiments not used for the identification. A summary of the experiments considered in the study is given in Table 1, with forcing scenarios shown in Fig. 1.

The variables taken for the identification of the response functions are the ones relevant for the quantification of the land carbon sensitivities $\gamma$ and $\beta$, respectively:

(a) the change in global land carbon in response to changes in global land temperature;

(b) the change in global land carbon in response to changes in atmospheric CO\textsubscript{2}.

Global land carbon is computed as the sum of the total land carbon over all grid cells of the model. Global land temperature is calculated as the mean near-surface air temperature over land at 2 m height. The changes are computed as $\Delta Y(t) = Y(t) - Y_{\text{PI}}$, with $Y_{\text{PI}}$ being the mean value of observable $Y$ from a control simulation at pre-industrial conditions. Since the main interest lies in long-term variations, annual mean data are used.

As demonstrated in Appendix C, the generalization of the $\beta$ sensitivity can be shown to be monotonic. Therefore, in the following we will derive it employing the additional noise-level adjustment in the RFI algorithm (step 6 of Fig. 1 in Part 1). Since the generalization of the $\gamma$ sensitivity is not known to be monotonic, for this sensitivity the RFI algorithm will be applied without the additional adjustment.

2.2 Estimating the linear regime from “percent” experiments

As described in Part 1, the recovery of response functions is complicated by the presence of noise and nonlinearities. The RFI method is designed to cope with the former. In the
Table 1. C⁴MIP-type experiments considered in this study. Forcings are shown in Fig. 1. Abbreviations “rad” and “bgc” refer to standard CMIP model setups used to calculate the climate-carbon cycle sensitivities. In the “rad” (radiatively coupled) setup only the radiation code of the model is affected by changes in atmospheric CO₂. This setup is used to calculate γ. In the “bgc” (biogeochemically coupled) setup only the biogeochemistry of the model is affected by changes in atmospheric CO₂. This setup is used to calculate β. In brackets are names of standard CMIP experiments.

Figure 1. Forcings for the C⁴MIP-type experiments considered in this study.

In the present section we present a technique to cope with the latter, but at the expense of performing additional response experiments. This technique will serve as a complement to the RFI method in the application to the land carbon cycle in the following sections. By these additional experiments we will determine the range of forcing strengths for which the response can be considered linear – an analysis in general not possible using only the control and perturbation experiments on which the RFI method is based.

Before we introduce this technique to cope with nonlinearities, it is useful to specify more clearly what we mean by “nonlinearity”. Dynamical systems like the Earth system are crowded with nonlinearities. Our notion of “nonlinearity” is much more specific: the linear response formula (Eq. 3) can be interpreted as the linear term in a Volterra expansion of the response ΔY(t) of the system into the perturbation Δf(t) (see Sect. 2 in Part 1). This expansion is given by

\[
\Delta Y(t) = \int_0^t \chi(t-s)\Delta f(s)ds + \eta(t) + \mathcal{O}(\Delta f)^2,
\]

where \(\mathcal{O}(\Delta f)^2\) represents terms of order 2 and higher in the perturbation \(\Delta f\). For small enough perturbations the term \(\mathcal{O}(\Delta f)^2\) is small compared to the linear-order term and can be ignored, so that Eq. (8) yields Eq. (3). Throughout this study, nonlinearities are defined as the nonlinear terms \(\mathcal{O}(\Delta f)^2\) in this expansion. Indeed, these nonlinear terms arise from the intrinsic nonlinearities of the underlying system. In the language of statistical mechanics one would call those intrinsic nonlinearities as “microscopic”. This in mind, our notions of linearity and nonlinearity should then be termed “macroscopic”. Since the idea here is to study the linear response of the system, we will be interested only in the case where perturbations are so small that the nonlinear terms \(\mathcal{O}(\Delta f)^2\) can be ignored. However, the question is whether they can be ignored. It is clear that nonlinearities may gain importance with increasing forcing strength. Hence, to study only the linear response, experiment data can be used for our purpose only up to such perturbation strengths where nonlinearity start to contribute to the response; i.e., we have to identify the regime where the response is still linear. This is the purpose of the technique that we describe in the following.

To introduce our technique we use the example of simulations with the linear toy model employed in Part 1. To

demonstrate the effect of nonlinearities on the recovery of \( \chi(t) \), following Part 1 we artificially add a nonlinear term \(-aY^2(t)\) to the linear response \( Y(t) \) of the toy model:

\[
Y_{\text{nonlin}}(t) := Y(t) - aY^2(t).
\]

In this way we obtain a nonlinear response \( Y_{\text{nonlin}}(t) \), with nonlinearity strength controlled by the parameter \( a \), from which \( \chi(t) \) is derived. In addition to including this nonlinear term in the toy model response, to introduce the technique we will need to quantify the quality of the recovery of the response function. Since in our application to the land carbon the “true” response function is not known a priori, following Part 1 we quantify the quality of the recovery indirectly by measuring the quality with which the recovered response function can predict the response of the model in experiments not used for the recovery itself. For this purpose we introduce the relative prediction error

\[
\varepsilon_k := \frac{||\Delta Y^k - \chi \star \Delta f^k||}{||\Delta Y^k||},
\]

where \( \star \) stands for the convolution operation, \( \Delta Y^k \) and \( \Delta f^k \) are the response and the perturbation in experiment “\( k \)”, and \( \chi \) is the response function recovered from the 1 % experiment.

We can now present our technique. Taking first a purely linear situation (\( a = 0 \)), we show in Fig. 2a the relative prediction error (Eq. 10) when using the response function obtained from a 1 % simulation to predict the response from two other % simulations with smaller growth rate. More precisely, performing a sequence of 1 % experiments for increasingly longer simulation periods, we calculated for each experiment the response function and used it to predict the response for a 0.5 % and 0.75 % experiment covering the same simulation period. Then we plotted in Fig. 2a the relative prediction error against the final forcing strength of the 1 % experiment. As a result, it is seen that with increasing final forcing strength the relative prediction error decreases. This happens because in this linear case the SNR is increasing with increasing simulation period, i.e., with increasing final forcing strength, so that the recovery of the response function continuously improves.

Calculating the relative prediction error only for experiments with smaller growth rate becomes important in the next case where nonlinearities are considered (Fig. 2b). This plot was obtained by the same procedure except that we took for the nonlinearity parameter a value \( a > 0 \). As seen, in this nonlinear case the relative prediction error is first improving but deteriorating afterwards. For small forcing, nonlinearities are small and therefore the relative prediction error behaves as in the linear case; i.e., it decreases with final forcing strength. However, when forcing strengths become larger, nonlinearities start to contribute substantially to the response, thereby causing a deterioration of the recovery of the response function and consequently the relative prediction error once more increases. This increase of the prediction error can be unambiguously traced back to the presence of nonlinearities in the 1 % simulation because the prediction error was calculated only for experiments with smaller growth rate, i.e., smaller forcing strength throughout the whole simulation. Therefore, nonlinearities contribute already substantially to the response in the 1 % simulation before they become relevant in the other experiments. Accordingly, with this type of experiment setup we can be sure that the increase in the prediction error comes solely from the deterioration of the recovery of the response function and not from nonlinearities in the additional experiments used for calculating the prediction error.

Obviously, for forcing strengths smaller than at the minimum, nonlinearities do not hinder the recovery of the response function, so that one can consider this to be the regime of linear system behavior. In view of the trade-off between noise and nonlinearities, for the 1 % experiment the response function is thus optimally recovered when taking as final forcing strength the value at the minimum of the prediction error curve. Similarly, if the error curve has no minimum (as in the linear case shown in Fig. 2a), the optimal recovery is obtained from the experiment with the largest forcing strength.

With the presentation of this additional technique to identify the linear regime we are ready for the application to the MPI-ESM in the next sections.

### 3 Generalized sensitivity \( \chi_\gamma \)

In this section we identify from MPI-ESM simulations the linear response function \( \chi_\gamma \) (generalized \( \gamma \) sensitivity), defined by

\[
\Delta C_{\text{rad}}(t) = \int_0^t \chi_\gamma(t - s) \Delta T(s) \, ds + \eta(t),
\]

where now the response is \( \Delta Y(t) := \Delta C_{\text{rad}}(t) \) and the forcing is \( \Delta f(t) := \Delta T(t) \), with \( \Delta C_{\text{rad}}(t) \) being the change in global land carbon obtained in the “rad” experiment (see Table 1) and \( \Delta T(t) \) the change in global land temperature.

That \( \chi_\gamma \) indeed generalizes \( \gamma \) can be understood by considering that \( \gamma \) is defined by

\[
\gamma(t) = \frac{\Delta C_{\text{rad}}(t)}{\Delta T(t)} = \frac{1}{\Delta T(t)} \int_0^t \chi_\gamma(t - s) \Delta T(s) \, ds,
\]

for a negligible noise \( \eta(t) \). From Eq. (12) it is clear that by knowing \( \chi_\gamma(t) \) one can compute the response \( \Delta C_{\text{rad}}(t) \) and thereby \( \gamma(t) \) for any time-dependent perturbation \( \Delta T(t) \), as long as the perturbation strength is small. Hence, \( \chi_\gamma(t) \) can be seen as a property of the land carbon system and a generalization of \( \gamma(t) \).
Figure 2. Toy model example for the identification of the linear regime by using additional experiments. Shown is the relative prediction error (Eq. 10) for the response of 0.5% and 0.75% experiments as obtained from the response function calculated by the RFI method from 1% experiments. The relative prediction errors are plotted against the final forcing strengths of a sequence of 1% experiments with increasing time series length. The crosses at the minima indicate the final forcing strength for which the response function is optimally recovered (see text). (a) shows the behavior for the fully linear toy model \((a = 0)\) and (b) the behavior in the presence of nonlinear contributions to the response \((a = 5 \times 10^{-5})\). For the purpose of demonstrating more clearly the increase in the relative prediction error for a decrease in the forcing strength, we include in the plot cases where the forcing strength is extremely small, corresponding to very small time series lengths. To deal with such cases, we set for a number of data points \(N < 30\) the number of timescales \(M = N\) (see parameters for the RFI method in Part 1). For such small number of timescales, usually no plateau in the singular values spectrum is found (step 2 of Fig. 1 in Part 1). Therefore, for these special cases we also modify the algorithm to interpret the two smallest singular values as a plateau, since their small magnitude makes them have a similar effect to those singular values belonging to the plateau itself. In addition, to illustrate the most general case where \(\chi(t)\) is not known to be monotonic, we exclude here the monotonicity check (step 6 of Fig. 1 in Part 1).

3.1 Estimating the linear regime

As a first step in obtaining a proper approximation of \(\chi_r(t)\), we investigate what maximum forcing strength can be used to ensure that the recovered \(\chi_r(t)\) is not spoiled by the presence of nonlinearities. Using the technique introduced in Sect. 2.2, we show in Fig. 3 the relative prediction error (Eq. 10) for \(\chi_r(t)\) recovered from the 1% rad experiment as a function of the final forcing strength in the 1% rad experiment. There is no clear minimum, so that for the data available the recovery of \(\chi_r(t)\) seems not to be limited by nonlinearities. For optimal recovery we thus take the full time series, i.e., the maximum final forcing strength.

3.2 \(\chi_r\) and the quality of its recovery

The quality of the recovery can in principle be improved by taking an experiment with better SNR. To investigate whether the recovery from the 1% rad experiment can be further improved, we also applied the RFI algorithm to recover \(\chi_r\) from the 2×CO\(_2\) rad experiment. We chose the 2×CO\(_2\) rad experiment because as shown in Fig. 4 it has smaller forcing strengths than the maximum forcing strength for the 1% rad experiment – therefore nonlinearities should also not limit the recovery – but is expected to carry useful information over a larger range of the response spectrum. This expectation can be justified as follows (MacMartin and Kravitz, 2016). Taking the Laplace transform of Eq. (11) gives

\[
\Delta \tilde{C}^{\text{rad}}(p) = \tilde{\chi}_r(p) \Delta \tilde{T}(p) + \tilde{\eta}(p),
\]

where the tilde denotes Laplace transformed functions. From Fig. 4 it is seen that for the 1% rad experiment the temperature \(\Delta T\) behaves approximately as a linear function, which gives a Laplace transform \(\Delta \tilde{T}(p)\) proportional to \(1/p^2\). For the 2×CO\(_2\) rad experiment, the temperature behaves approximately as a step function (ignoring the transient in the first 20 years), which gives a Laplace transform \(\Delta \tilde{T}(p)\) proportional to \(1/p\). This means that for the same \(\chi_r\), the first term on the right-hand side of Eq. (13) – the “clean” response – decays to zero faster for the 1% rad experiment than for the 2×CO\(_2\) rad experiment. Hence, assuming the same noise \(\eta\)
for both cases, the response from the 2×CO₂ rad experiment is buried in the noise only at larger $p$, meaning that this experiment carries useful information until higher rate values $p$ than the response from the 1 % rad experiment.

The response function $\chi_r(t)$ recovered from the two types of experiments is shown in Fig. 5a. As expected, the different experiments indeed result in different recoveries. Because we know from the analysis of Fig. 3 that nonlinearities do not limit the recovery, the difference between the two response functions probably results from the difference in the quality of the data from the two types of experiments. To compare the robustness of each recovery, we analyze how well they predict the response from other experiments (Fig. 5b and c). If the response function is correctly recovered, it should be able to predict not only experiments with smaller, but also experiments with higher forcing rates. Therefore, we also include in the analysis 1.5 % and 2 % rad experiments. To exclude errors that may be caused by nonlinearity, we take as a conservative estimate of the linear regime forcing strengths smaller than the final forcing strength at the end of the 1 % rad experiment (which is approximately the maximum forcing strength; see temperature value at $t = 140$ years for the 1 % rad experiment in Fig. 4). We take these values as an estimate of the linear regime because the 1 % rad experiment has only 140 years, so that no estimate for higher forcing strengths is available. Hence, for the 1.5 % and 2 % rad experiments the responses are expected to be reasonably predictable at least until the values marked with circles, where their respective forcing strengths reach this maximum forcing strength. All other experiments have forcing strengths smaller or equal to this maximum forcing strength, so that they should be predictable for the whole time series.

Figure 5b shows the quality of the prediction using $\chi_r(t)$ recovered from the 1 % rad experiment. Visually, model response and prediction seem to have a comparable quality of agreement across the 1.1×CO₂, 0.5 %, 0.75 % and 1.5 % rad experiments, while for the 2 % and 2×CO₂ rad experiments there are larger discrepancies. For a quantitative analysis, we compute for the estimated linear regime the relative prediction error (Eq. 10) for each experiment (right side of the plot). It is seen that the error varies from less than 10 % for the 0.75 % and 1.5 % rad experiments to values between 10 % and 20 % for the 0.5 %, 2 % and 2×CO₂ rad experiments, and a significantly larger value of 57 % for the 1.1×CO₂ rad experiment. To better understand these differences, it is important to note that as long as nonlinearities are small, experiments with higher forcing strength are expected to have smaller prediction error because they have higher SNR. This can be made plausible by considering that a perfectly recovered response function predicts a “clean” linear response (infinite SNR) with zero error, whereas the same response function can predict a noisy response only with some finite error. Therefore, if $\chi_r(t)$ is well recovered, we expect large prediction errors for experiments with small forcing strengths such as the 1.1×CO₂ rad – which is indeed the case – but small errors for experiments with large forcing strengths but still well within the linear regime such as the 2×CO₂ rad (compare the forcing strengths for the 2×CO₂ rad experiment and the maximum forcing strength for the 1 % rad experiment in Fig. 4). Since contrarily to the expectation the prediction error is not particularly small for the 2×CO₂ rad experiment, probably the recovery of $\chi_r(t)$ derived from the 1 % rad experiment is not completely accurate and may still be further improved. As suggested above, such improvement may be achieved by taking data with better quality from the 2×CO₂ rad experiment.

Figure 5c shows the quality of the prediction using $\chi_r(t)$ recovered from the 2×CO₂ rad experiment. As expected, results indicate an improvement in the recovery (compare to Fig. 5b). The prediction error decreases for all experiments present in both plots. In addition, it also decreases if we compare the prediction of the 1 % rad response in Fig. 5c with that of the 2×CO₂ rad response in Fig. 5b.

This section therefore suggests two main conclusions: first, for $\chi_r(t)$ the response seems to be approximately linear for temperature perturbations up to at least 6 K. Second, the overall improvement of the prediction in Fig. 5c compared to Fig. 5b confirms the expectation from the Laplace transform analysis that the step-like 2×CO₂ rad experiment indeed carries more information on the response function than the 1 % rad experiment. This suggests that step-like experiments may be more appropriate than the standard 1 % experiment for the identification of linear response functions.

### 4 Generalized sensitivity $\chi_\beta$

In this section we identify the linear response function $\chi_\beta$ (generalized $\beta$ sensitivity), defined by

$$\Delta C^{\text{bgc}}(t) = \int_0^t \chi_\beta(t-s) \Delta C_{\text{atm}}(s) ds + \eta(t),$$

where $\Delta C^{\text{bgc}}(t)$ is the difference between the observed and the predicted concentrations, $\Delta C_{\text{atm}}(s)$ is the atmospheric change, and $\eta(t)$ is the error term.
**Figure 5.** $\chi_y$ recovered from 1% and 2×CO$_2$ rad experiments (a) and prediction of model responses using these recoveries of $\chi_y$. Circles indicate the maximum value for which 1.5% and 2% responses are predictable according to the estimate of the linear regime (see text). At the right of (b, c) the relative prediction error (see Eq. 10) is indicated for the different experiments, calculated for the 1.5% and 2% rad experiments by considering only values preceding the circles.

where now the response is $\Delta Y(t) := \Delta C^{bgc}(t)$ and the forcing is $\Delta f(t) := \Delta C^{atm}(t)$, with $\Delta C^{bgc}(t)$ being the change in global land carbon found in the “bgc” experiment and $\Delta C^{atm}(t)$ the change in atmospheric CO$_2$ (and not atmospheric carbon content, as might be expected from the notation).

That $\chi_{\beta}$ indeed generalizes $\beta$ can be understood analogously to Sect. 3 by considering that $\beta(t)$ is defined by

$$
\beta(t) = \frac{\Delta C^{bgc}(t)}{\Delta C^{atm}(t)}
$$

for a negligible noise $\eta(t)$. Hence, $\chi_{\beta}(t)$ can be seen as a generalization of $\beta(t)$ and a property of the land carbon cycle that characterizes the response $\Delta C^{bgc}(t)$ to any time-dependent perturbation $\Delta C^{atm}(t)$, as long as the perturbation strength is small.

### 4.1 Approaches to identify $\chi_{\beta}$

Similarly to the last section, we identify $\chi_{\beta}(t)$ by several approaches to find the one that gives results with the best quality. For this purpose, we also consider in addition to Eq. (14) alternative formulas to derive $\chi_{\beta}(t)$, each taking a different forcing. The identification is performed in three different ways:

1. Using CO$_2$ as forcing (see Eq. 14);
2. Using the logarithm of CO$_2$ as forcing:

$$
\Delta C^{bgc}(t) = \int_0^t \chi_{\beta}(t-s) \Delta C^{atm}(s) \, ds + \eta(t),
$$

where now the forcing is

$$
\Delta f(t) := C^0_{atm} \ln \left( \frac{C_{atm}(t)}{C^0_{atm}} \right),
$$

with $C^0_{atm}$ being the pre-industrial value for atmospheric CO$_2$;

3. Using net primary production (NPP) as forcing:

$$
\Delta C^{bgc}(t) = \int_0^t \chi_{NPP}(t-s) \Delta NPP(C_{atm}(s)) \, ds + \eta(t).
$$

The first approach is the same used throughout the paper: \( \chi_{\beta}(t) \) is identified using the \( \Delta C_{\text{atm}}(t) \) forcing from Eq. (14).

The second and third approaches are motivated as follows. In the “bgc” setup, changes of atmospheric CO\(_2\) affect land carbon exclusively via the resulting changes in primary productivity\(^1\). Therefore, the reaction of land carbon to CO\(_2\) perturbations may be understood as a two-step process: first, CO\(_2\) affects primary productivity (carbon assimilation); second, the assimilated carbon adds to land carbon storage. This second step is in models typically described by an almost linear system of storage compartment forced by NPP (see, e.g., Xia et al., 2013; Huang et al., 2018). Thus, presumably the response of land carbon to NPP is well described by a linear response function. These considerations underline the second and third approaches but are more explicitly realized in the latter: there we first derive the linear response function \( \chi_{\text{NPP}}(t) \) describing the response of land carbon to changes in NPP, and then use the data of the simulated dependence of NPP on CO\(_2\) to derive the desired response function \( \chi_{\beta}(t) \) (see Eq. 21). In this way we try to keep the most critical step in the identification of the response function, namely the inversion of the response integral, largely free from nonlinearities, and indeed, for this reduced problem, without much interference from nonlinearity we can recover the response function from experiment data obtained for much higher perturbation strengths than in the first approach, and because of the higher SNR the quality of recovery is thereby largely improved (see below). Instead of NPP one could also try to split off the nonlinear part by taking GPP (gross primary production), which differs from NPP only by the autotrophic respiration. However, autotrophic respiration is lost to the atmosphere, so that it is NPP and not GPP that adds to land carbon storage. Thus, by taking NPP instead of GPP the linear part is arguably split off more completely. The second approach is motivated in the same way, except that the nonlinear part is guessed to be a logarithmic function of CO\(_2\) as suggested by the Keeling formula (see, e.g., Alexandrov et al., 2003), so that here no additional NPP data are needed from simulations.

Mathematically, our procedure in each approach is the following. In the second approach (see Eq. 16), we employ as forcing a logarithmic expression because it is known that a large part of the nonlinear relation between CO\(_2\) and carbon storage comes from the approximately logarithmic dependence of NPP on CO\(_2\) (e.g., Alexandrov et al., 2003). Such formula has the advantage that the expansion of the forcing in \( C_{\text{atm}} \) gives

\[
\Delta C_{\text{bgc}}(t) = \int_0^t \chi_{\beta}(t - s) \Delta C_{\text{atm}}(s) ds + \mathcal{O}((\Delta C_{\text{atm}})^2) + \eta(t). \tag{18}
\]

Taking \( \Delta C_{\text{atm}} \) sufficiently small and comparing the result to Eq. (14) thus yields

\[
\chi_{\beta}(t) = \chi_{\beta}^{\text{ln}}(t). \tag{19}
\]

Accordingly, the response function \( \chi_{\beta}^{\text{ln}}(t) \) from Eq. (16) also gives the desired \( \chi_{\beta}(t) \).

In the third approach, we take directly the response to NPP (see Eq. 17). Expanding the forcing \( \Delta \text{NPP}(C_{\text{atm}}) \) in \( C_{\text{atm}} \) gives

\[
\Delta C_{\text{bgc}}(t) = \int_0^t \chi_{\text{NPP}}(t - s) \frac{\partial \text{NPP}}{\partial C_{\text{atm}}} \bigg|_{C_{\text{atm}} = C_{\text{atm}}^0} \Delta C_{\text{atm}}(s) ds + \mathcal{O}((\Delta C_{\text{atm}})^2) + \eta(t). \tag{20}
\]

Taking \( \Delta C_{\text{atm}} \) sufficiently small and comparing the result to Eq. (14) yields

\[
\chi_{\beta}(t) = \chi_{\text{NPP}}(t) \frac{\partial \text{NPP}}{\partial C_{\text{atm}}} \bigg|_{C_{\text{atm}} = C_{\text{atm}}^0}. \tag{21}
\]

Accordingly, by this approach we compute \( \chi_{\beta}(t) \) in three steps: first, we identify the response function \( \chi_{\text{NPP}}(t) \) using Eq. (17); second, we take the first derivative of NPP with respect to CO\(_2\) at \( C_{\text{atm}} = C_{\text{atm}}^0 \); third, we apply Eq. (21) to obtain \( \chi_{\beta}(t) \) from \( \chi_{\text{NPP}}(t) \).

4.2 Checking nonlinearities with the three approaches

Before analyzing the recovery of \( \chi_{\beta}(t) \) employing the three approaches, one must verify that these two additional approaches indeed account for some of the nonlinearities in the response. If this is true, response formulas (Eqs. 16 and 17) should be able to predict the response to larger perturbation strengths than Eq. (14). To verify this expectation, in the following we compare the relative prediction error (Eq. 10) by applying Eqs. (14), (16) and (17).

Figure 6a shows the relative prediction error for \( \chi_{\beta}(t) \) recovered from the 1 % bgc experiment with the first approach (Eq. 14). The prediction is also computed via Eq. (14). The clear minima indicate the presence of strong nonlinearities for forcing strengths above around 100 ppm (94 ppm for the 0.5 % and 133 ppm for the 0.75 %). Therefore, in contrast to the case of \( \chi_{\gamma} \) discussed in the last section, we see here that one indeed has to cope with the additional difficulty of nonlinearities.

Figure 6b shows the prediction error when using \( \chi_{\beta}^{\text{ln}}(t) \) recovered from the 1 % bgc experiment with the second ap-
we took data from the 1% bgc experiment until the CO$_2$ was identified by the three approaches. For the identification, we employ the third approach, also suggested that this type of experiment may carry more information for the identification, we employ the third approach, also taking the 2×CO$_2$ bgc experiment. For the present application where the recovery is limited by nonlinearities, taking the 2×CO$_2$ bgc experiment has the additional advantage that because its forcing strength has a constant value throughout the whole experiment, we can use the full time series (140 years). To compute the first derivative of NPP with respect to CO$_2$ (second step of the third approach), we fitted the function NPP = NPP(C$_{atm}$) to polynomials of order 4, 5, and 6 and then took the first derivative from the fits.

The results from the three approaches are shown in Fig. 7a. At short timescales there is an overall agreement among all recoveries with only small discrepancies. It is not possible to compare the results also for longer timescales, we extend the response functions recovered from the 1% bgc experiment obtained from time series with 30, 40, and 70 years, respectively, for the first, second, and third approaches — until 140 years (extensions are indicated by dotted lines). This can be done because with the RFI method we derive the response function from the ansatz (5), which formally gives the values of the response function for all times. The result is that all response functions recovered from the 1% bgc experiment present relatively small discrepancies even at long timescales. Response functions derived from the 2×CO$_2$ bgc experiment with the third approach show a similar behavior among themselves but differ from the recoveries using the 1% bgc experiment. The reason for this difference will be investigated below.

To quantitatively compare the quality of the recoveries, we plotted in Fig. 7b the relative prediction error (Eq. 10). Since the response functions were derived using different time series lengths, for a fair comparison we compute the error only at the minimal time series length of 30 years (the time series length used for the first approach). Results show no large discrepancies among the different approaches. For the third approach, there seems to be a small advantage in using a polynomial of order 6 for the computation of the derivative.

However, results from Fig. 7b reflect only the quality of the recoveries at short timescales, for which anyway no large discrepancies were encountered in Fig. 7a. To evaluate the quality of the recovery also at long timescales, one must take

4.3 $\chi_\beta$ and the quality of its recovery

So far, we have only considered the ability of Eqs. (14), (16) and (17) to predict the land carbon response. Now, we analyze how well the generalized sensitivity $\chi_\beta(t)$ can be identified by the three approaches. For the identification we took data from the 1% bgc experiment until the CO$_2$ forcing strength reaches the first minimum for each case in Fig. 6: $\Delta C_{atm} = 94$ ppm for the first approach (30 years); $\Delta C_{atm} = 133$ ppm for the second approach (40 years); and $\Delta C_{atm} = 279$ ppm for the third approach (70 years). Since $\Delta C_{atm} = 279$ ppm is approximately the forcing strength for the 2×CO$_2$ bgc experiment and results from last section suggested that this type of experiment may carry more information for the identification, we employ the third approach, also taking the 2×CO$_2$ bgc experiment. For the present application where the recovery is limited by nonlinearities, taking the 2×CO$_2$ bgc experiment has the additional advantage that because its forcing strength has a constant value throughout the whole experiment, we can use the full time series (140 years). To compute the first derivative of NPP with respect to CO$_2$ (second step of the third approach), we fitted the function NPP = NPP(C$_{atm}$) to polynomials of order 4, 5, and 6 and then took the first derivative from the fits.

The results from the three approaches are shown in Fig. 7a. At short timescales there is an overall agreement among all recoveries with only small discrepancies. To be able to compare the results also for longer timescales, we extend the response functions recovered from the 1% bgc experiment — obtained from time series with 30, 40, and 70 years, respectively, for the first, second, and third approaches — until 140 years (extensions are indicated by dotted lines). This can be done because with the RFI method we derive the response function from the ansatz (5), which formally gives the values of the response function for all times. The result is that all response functions recovered from the 1% bgc experiment present relatively small discrepancies even at long timescales. Response functions derived from the 2×CO$_2$ bgc experiment with the third approach show a similar behavior among themselves but differ from the recoveries using the 1% bgc experiment. The reason for this difference will be investigated below.

To quantitatively compare the quality of the recoveries, we plotted in Fig. 7b the relative prediction error (Eq. 10). Since the response functions were derived using different time series lengths, for a fair comparison we compute the error only at the minimal time series length of 30 years (the time series length used for the first approach). Results show no large discrepancies among the different approaches. For the third approach, there seems to be a small advantage in using a polynomial of order 6 for the computation of the derivative.

However, results from Fig. 7b reflect only the quality of the recoveries at short timescales, for which anyway no large discrepancies were encountered in Fig. 7a. To evaluate the quality of the recovery also at long timescales, one must take
Figure 7. Response function $\chi_\beta(t)$ derived by the three approaches (a) and the respective prediction errors for the first 30 years of the response (b). $\Delta C\text{atm}^{1%}$: recovery with first approach from 1% bgc experiment; log$(C\text{atm})^{1%}$: recovery with second approach from the 1% bgc experiment; NPP$^{1%}\text{pol}$: recovery with third approach from the 1% bgc experiment using for the derivative a polynomial fit of order $x$; NPP$^{2\times}\text{pol}$: recovery with third approach from the 2$\times$CO$_2$ bgc experiment using for the derivative a polynomial fit of order $x$. Continuous lines denote values of $\chi(t)$ that are within the time series length used for the recovery (30 years for $\Delta C\text{atm}^{1%}$, 40 years for log$(C\text{atm})^{1%}$ and 70 years for NPP$^{1%}\text{pol}$). Dotted lines denote extended parts of the response function, i.e., values not covered by the time series used for the recovery but obtained from the recovered spectrum using Eq. (5). Circles denote the response functions derived taking the full time series (NPP$^{2\times}\text{pol}$). For more details, see text.

The extended version of the response functions that were derived from shorter time series. Since the only substantial difference at long timescales in Fig. 7a is found between the response functions recovered from the 1% and 2$\times$CO$_2$ bgc experiments, we take for this analysis exemplary only the response functions recovered with the first approach (1% bgc experiment) and the third approach (2$\times$CO$_2$ bgc experiment). By choosing the response function recovered with the first approach, we evaluate for the worst case scenario (where only 30 years are used for the recovery) how reliable predictions are for timescales longer than the time series used for recovery. In contrast, by choosing the response function recovered with the third approach from the 2$\times$CO$_2$ bgc experiment, we check whether the different values at long timescales are actually an improvement in the recovery. As mentioned above, such improvement is expected because this response function was recovered taking the full time series (140 years).

Following the same procedure as in the last section, in Fig. 8 we show the quality of the prediction for different experiments using the aforementioned recoveries of $\chi_\beta(t)$. Figure 8a shows the results for the predictions calculated via Eq. (14) using $\chi_\beta(t)$ recovered with the first approach. We take as an estimate of the linear regime forcing strengths...
smaller than the forcing strength at the first minimum in Fig. 6a. The response values corresponding to this forcing strength are marked in Fig. 8a with circles. It is seen that although $\chi_{\beta}(t)$ was recovered using a time series of only 30 years, it predicts the $1.1 \times CO_2$ bgc experiment with only 3% error over 140 years. Other experiments are predicted within the linear regime with error smaller than 10% with exception of the 2% bgc experiment, for which the error is around 14%. Since the $2 \times CO_2$ has a constant forcing strength outside the linear regime already from the beginning, its prediction fails as expected for the whole time series.

In Fig. 8a we could only evaluate the quality of the long timescales of $\chi_{\beta}(t)$ by the prediction of the $1.1 \times CO_2$ bgc experiment, because this is the only experiment which has forcing strengths within the linear regime over the whole time series. To check the ability of $\chi_{\beta}(t)$ to predict also other experiments at long timescales, we account for some of the nonlinearity in the response by taking NPP instead of CO$_2$ as forcing (see discussion of Fig. 6). Therefore, we perform the prediction by employing Eq. (17) instead of Eq. (14). Since for employing Eq. (17) one needs $\chi_{NPP}(t)$ and not $\chi_{\beta}(t)$, we take the $\chi_{\beta}(t)$ derived with the first approach and compute $\chi_{NPP}(t)$ from it via Eq. (21). Because the conversion from $\chi_{\beta}(t)$ to $\chi_{NPP}(t)$ is a simple scaling, the timescales structure is maintained. Hence, we can evaluate the quality of the recovered $\chi_{\beta}(t)$ from the results given by the obtained $\chi_{NPP}(t)$.

The prediction results computed via Eq. (17) with the obtained $\chi_{NPP}(t)$ are shown in Fig. 8b. Because errors at the minima in Fig. 6c are not substantially smaller than those at the maximum final forcing strength, we take as an estimate of the linear regime all values smaller than the last value of NPP for the 1% bgc experiment (marked with circles in the responses). Once again it is seen that although $\chi_{\beta}(t)$ was recovered using a time series of 30 years, after conversion to $\chi_{NPP}(t)$ almost all experiments can be predicted with less than 10% error for the whole time series. The 1.5% and 2% bgc experiments are predicted with errors of 17% and 4% within the linear regime. Results from Fig. 8a and b therefore suggest that although nonlinearities do restrict the recovery from Eq. (14), taking experiments with forcing strengths within the linear regime for the recovery leads to reliable prediction results even for times reasonably longer than the length of the time series from which the response function was recovered.

Finally, we investigate whether the different values seen in Fig. 7a for the $\chi_{\beta}(t)$ recovered from the $2 \times CO_2$ bgc experiment indeed reflect a better quality of recovery. Following the same reasoning that led to Fig. 8b, since in the third approach $\chi_{\beta}(t)$ is obtained from a scaling of $\chi_{NPP}(t)$, we evaluate the quality of $\chi_{\beta}(t)$ from the results given by $\chi_{NPP}(t)$. Accordingly, in Fig. 8c we plot the prediction via Eq. (17) using the $\chi_{NPP}(t)$ recovered from the $2 \times CO_2$ bgc experiment. As expected, the overall prediction indeed improves compared to Fig. 8b. Individual relative prediction errors decrease for all experiments, with the exception of the $1.1 \times CO_2$. Since the response functions used for Fig. 8b and c differ only at long timescales, this improvement suggests that obtaining $\chi_{\beta}(t)$ from the $2 \times CO_2$ bgc experiment indeed gives a better recovery over these timescales. Further, because all recoveries are similar at short timescales (see Fig. 7a), overall this recovery shows the best quality.

5 Spectrum of land carbon timescales

A response function obtained with high quality not only results in more accurate predictions, but may also provide valuable information about the internal dynamics of the system. For the case of $\chi_{\beta}(t)$, we find that the recovery with best quality gives a relatively detailed description of the spectrum of land carbon timescales (see Eq. 5). In this section, we investigate (i) the robustness of this result and (ii) the explanation for the structure of the obtained spectrum. The robustness of this detailed spectrum must be analyzed because, as explained in Part 1, the problem of recovering the spectrum of timescales from data is ill-posed, so that in principle it is not clear to what extent the recovered spectrum can be trusted. To investigate this robustness, we check whether the main characteristics of the spectrum recovered by our RFI algorithm can also be obtained by two independent methods: a Gregory-plot approach (Gregory et al., 2004) and an approach that combines regional responses for the tropics and extra-tropics. Since the best recovery of $\chi_{\beta}(t)$ was obtained from the response to NPP for the $2 \times CO_2$ bgc experiment, in our investigations we will study only this case.

5.1 Obtaining the detailed spectrum

However, before we investigate the recovered spectrum, we demonstrate how such a detailed structure may arise from a better recovery of the response function. In Fig. 9a we plot the spectrum $q(\tau)$ of the response function used for Fig. 8b, i.e., $\chi_{\beta}(t)$ recovered with the first approach (see beginning of Sect. 4) and converted to $\chi_{NPP}(t)$ via Eq. (21). Because the data used for the recovery have a relatively low quality – the response function was recovered from the 1% bgc experiment taken for only 30 years – regularization filters out most of the SVD components of the spectrum in Eq. (6). Since the low-index SVD components that are not filtered out tend to be smooth (Hansen, 1989, 1990, see also Part 1), the final result of this filtering is the smooth spectrum seen in Fig. 9a. Obviously, although this smooth spectrum is a sufficiently good approximation to make the predictions shown in Fig. 8b, it is not very informative about the internal timescale structure. Instead, the spectrum of the response function $\chi_{NPP}(t)$ used for Fig. 8c has a more detailed structure (Fig. 9b). In this case, the higher quality of the data used for the identification ($2 \times CO_2$ bgc experiment taken for 140 years) results in less filtering by regularization, thereby
revealing more details of the underlying spectrum. The result is a spectrum with two peak timescales, at around 4 and 100 years.  

5.2 Checking the robustness of the spectrum via a Gregory-type approach

Some trust in this result may be gained via a linear-regression procedure following the same logic underlying a “Gregory plot” (Gregory et al., 2004) but applied here not to radiative forcing but to land carbon. As for a Gregory plot, we look here at how the nonequilibrium fluxes relax to equilibrium after a step-type perturbation. In our case this is the 2×CO₂ bgc experiment. The idea here is to try to identify from an independent method important timescales in the response, so that they can be compared against the spectrum in Fig. 9b. For this analysis, we plot the global land carbon against its first time derivative (this is the net land–atmosphere carbon flux). Using the 2×CO₂ bgc experiment where the forcing is constant, the first time derivative vanishes as the land carbon approaches a new equilibrium value. The rate at which the derivative changes can be associated with a timescale $τ_i$, which should show up with a large weight value $q_i$ in the spectrum. Interestingly, the plot shows that the transient behavior towards equilibrium develops approximately at two different rates: a higher rate from the starting point until around 3520 Pg C, and a lower rate from 3520 Pg C onwards. To determine these rate values, we fitted a linear func-

---

2We ignore the negative values obtained for timescales smaller than 1 year (data time step) and larger than 140 years (time series length) because spectral contributions at timescales much longer or much shorter than the timescales covered by data cannot be correctly recovered. Yet, as demonstrated in Appendix D, their wrong recovery does not strongly affect the recovered response function, so that they can be safely ignored. Other slightly negative values between the two peaks are probably small recovery errors that inevitably appear as a consequence of ill-posedness and the filtering by regularization (such slightly negative values have also been observed in recovered spectra shown in Appendix E).
tion $dC/dt = a + bC_{\text{bgc}}$ for each of these two ranges of the land carbon. Then, from each rate value $b$ we computed a timescale by $\tau = -1/b$. The computed timescales taking 1 standard deviation into account are shown by the two ranges highlighted in Fig. 9b. As seen, this linear-regression procedure also reveals a timescale structure dominated by two timescales. While the shortest timescale peak of the spectrum partially overlaps with the corresponding timescale range from the linear-regression plot, the longest timescale peak is almost perfectly matched. This result suggests that the recovered spectrum indeed reflects internal characteristics of the global response of the land carbon cycle.

5.3 Checking the robustness of the spectrum via regional response functions

The robustness of this detailed spectrum can be further checked by a different method. In the following, we test this robustness by checking the consistency between the timescales of global and regional carbon responses.

To study regional carbon responses, we considered two regions: tropics and extra-tropics. Tropics were defined as the region between latitudes $30^\circ$ S and $30^\circ$ N, and extra-tropics as the remaining part of the globe. We then determined separately the linear response functions that characterize the land carbon response to NPP in the tropics and extra-tropics, defined, respectively, by

$$
\Delta C_{\text{bgc}, \text{tr}}(t) = \int_0^t \chi_{\text{NPP}}^{\text{tr}}(t - s) \Delta \text{NPP}^{\text{tr}}(s) ds + \eta^{\text{tr}}(t),
$$

$$
\Delta C_{\text{bgc}, \text{et}}(t) = \int_0^t \chi_{\text{NPP}}^{\text{et}}(t - s) \Delta \text{NPP}^{\text{et}}(s) ds + \eta^{\text{et}}(t).
$$

The data were taken once more from the $2 \times \text{CO}_2$ bgc experiment.

Before assessing the robustness of the spectrum, we check the consistency between the regional and global response functions. In this test, we show that the global response function $\chi_{\text{NPP}}^{\text{et}}$ can be reconstructed by combining $\chi_{\text{NPP}}^{\text{tr}}$ and $\chi_{\text{NPP}}^{\text{et}}$. For this purpose, we write the global land carbon as the sum of the land carbon in the tropics and extra-tropics:

$$
\Delta C_{\text{bgc}}(t) = \Delta C_{\text{bgc}, \text{tr}}(t) + \Delta C_{\text{bgc}, \text{et}}(t).
$$

Applying a Laplace transform to both sides of Eq. (25) and reorganizing the resulting equation gives

$$
\tilde{\chi}_{\text{NPP}}(p) = \frac{\tilde{\chi}_{\text{NPP}}^{\text{tr}}(p) \Delta \text{NPP}^{\text{tr}}(p) + \tilde{\chi}_{\text{NPP}}^{\text{et}}(p) \Delta \text{NPP}^{\text{et}}(p)}{\Delta \text{NPP}(p)}.
$$

Therefore, the Laplace transformed $\tilde{\chi}_{\text{NPP}}(p)$ can be obtained from combining the NPP forcings and the response functions for the tropics and extra-tropics. Hence, if the response functions are correctly recovered by the RFI algorithm, Eq. (26) should hold at least approximately. In order to check this, we computed the Laplace transforms analytically by approximating the NPP forcings by step functions (since we take the $2 \times \text{CO}_2$ bgc experiment), and using Eq. (5) for the response functions. Figure 10a shows the quality of the result. The small discrepancy between $\tilde{\chi}_{\text{NPP}}(p)$ obtained from the global carbon response and from combining the regional responses can be at least partially explained by the approximation error made to represent the forcings by a step function.

We now check the robustness of the land carbon spectrum by combining $\chi_{\text{NPP}}^{\text{tr}}(t)$ and $\chi_{\text{NPP}}^{\text{et}}(t)$ to obtain $\chi^{B}(t)$ and thereby $q^{B}(t)$. To this end, we first obtain the tropical $\chi^{B}(t)$ and extra-tropical $\chi^{B}(t)$ by applying Eq. (21):

$$
\chi^{\text{tr}}(t) = \frac{\partial \text{NPP}^{\text{tr}}}{\partial C_{\text{atm}}} \bigg|_{C_{\text{atm}} = C_{\text{atm}}^{0}} \chi_{\text{NPP}}^{\text{tr}}(t),
$$

$$
\chi^{\text{et}}(t) = \frac{\partial \text{NPP}^{\text{et}}}{\partial C_{\text{atm}}} \bigg|_{C_{\text{atm}} = C_{\text{atm}}^{0}} \chi_{\text{NPP}}^{\text{et}}(t).
$$

Note that because $\text{CO}_2$ is well mixed, $\Delta C_{\text{atm}}^{\text{tr}}(t) \approx \Delta C_{\text{atm}}^{\text{et}}(t) \approx \Delta C_{\text{atm}}(t)$, so that, by characterizing the tropical and the extra-tropical response to $\text{CO}_2$, $\chi^{B}(t)$ and $\chi^{B}(t)$ are describing the response to a regionally correct perturbation. Using the response functions obtained from Eqs. (27) and (28), one can now write Eq. (14) for global, tropical and

https://doi.org/10.5194/npg-28-533-2021

Nonlin. Processes Geophys., 28, 533–564, 2021
Figure 9. Spectra associated with $\chi_{\text{NPP}}$ derived with different resolutions and a Gregory-type plot to identify the timescale structure of land carbon. (a) Spectrum derived with the first approach (taking CO$_2$ as forcing) from the 1% bgc experiment; (b) spectrum derived with the third approach (taking NPP as forcing) from the 2×CO$_2$ bgc experiment; (c) Gregory-type plot of global land carbon against land–atmosphere carbon flux. Dots are the data, with the color scale from white to black indicating the evolution from 1 to 140 years. Values of $b$ indicate the rate at which the time derivative of land carbon changes with respect to the land carbon itself. Ranges of timescales corresponding to each rate accounting for 1 standard deviation are shown in (b).

Extra-tropical carbon. Plugging the result into Eq. (24) gives

$$\int_0^t \chi_{\beta}(t-s) \Delta C_{\text{atm}}(s) ds = \int_0^t [\chi_{\text{tr}}^\beta(t-s) + \chi_{\text{et}}^\beta(t-s)] \Delta C_{\text{atm}}(s) ds. \tag{29}$$

Hence, one can infer that

$$\chi_{\beta}(t) = \chi_{\text{tr}}^\beta(t) + \chi_{\text{et}}^\beta(t). \tag{30}$$

Therefore, the global response function $\chi_{\beta}(t)$ can be obtained from $\chi_{\text{tr}}^\beta(t)$ and $\chi_{\text{et}}^\beta(t)$. However, in addition, since $\chi(t)$ is given by Eq. (5), Eq. (30) implies that one can also obtain the global spectrum $q_{\beta}(\tau)$ by combining the regional spectra:

$$q_{\beta}(\tau) = q_{\text{tr}}^\beta(\tau) + q_{\text{et}}^\beta(\tau). \tag{31}$$

Therefore, using the recovered response functions for tropical and extra-tropical carbon one can obtain the global response function $\chi_{\beta}$ and its associated spectrum $q_{\beta}$. Accordingly, in this test we check Eqs. (30) and (31). For the calculation of the derivatives in Eqs. (27) and (28) we fitted $\text{NPP}^\beta = \text{NPP}^\beta(C_{\text{atm}})$ and $\text{NPP}^\text{et} = \text{NPP}^\text{et}(C_{\text{atm}})$ once again by a polynomial of order 6 (which obtained the best results for global NPP in Fig. 7b) and took the derivatives from the fits. For $\chi_{\beta}(t)$ we used the recovery with best quality from Fig. 7 (“$\text{NPP}^\beta_{\text{pol6}}$”). The spectra $q_{\beta}(\tau)$, $q_{\text{tr}}^\beta(\tau)$ and $q_{\text{et}}^\beta(\tau)$ are obtained by scaling the spectra from $\chi_{\text{NPP}}(t)$, $\chi_{\text{NPP}}^\text{tr}(t)$ and $\chi_{\text{NPP}}^\text{et}(t)$ by the respective derivatives $\frac{\partial \text{NPP}}{\partial C_{\text{atm}}} \bigg|_{C_{\text{atm}} = C_{\text{atm}}^0}$, $\frac{\partial \text{NPP}^\beta}{\partial C_{\text{atm}}} \bigg|_{C_{\text{atm}} = C_{\text{atm}}^0}$ and $\frac{\partial \text{NPP}^\text{et}}{\partial C_{\text{atm}}} \bigg|_{C_{\text{atm}} = C_{\text{atm}}^0}$. Results are shown for $\chi_{\beta}$ in Fig. 10b and for $q_{\beta}$ in Fig. 10c. As seen in Fig. 10b, the reconstruction matches almost perfectly the values of $\chi_{\beta}$ for times beyond about 20 years. Likewise, the spectrum $q_{\beta}$ is almost perfectly reconstructed for timescales above 6 years, with a slight discrepancy between 15 and 25 years (see Fig. 10c). A larger disagreement is seen below 20 years for $\chi_{\beta}$ and below 6 years for $q_{\beta}$. One of the reasons is that only little information is available for timescales smaller than 1 year because this is the time step taken for the data.
However, Appendix D shows that timescales much shorter than the time step affect only \( \chi(0) \). The main reason for the disagreement is that high frequencies (and thus small timescales) are the most problematic to recover due to the ill-posedness of the problem that obscures the signal particularly at high frequencies.

Despite the disagreement at small timescales, Fig. 10b and c add confidence that (1) the response functions for global, tropical and extra-tropical carbon can be trusted over mid to long timescales (Fig. 10b) and that (2) the two-peak spectrum obtained for global land carbon indeed characterizes the response, since its computation from two independent approaches (combining regional spectra in Fig. 10c and the Gregory-type plot in Fig. 9c) yield similar results with characteristic timescales matching the peaks of the spectrum.

5.4 Investigating the two-peak structure of the spectrum

The reasons for the two-peak structure of the land carbon spectrum are conceivable. In principle, one possibility could be that the short timescales reflect the carbon dynamics in the tropics, a region with higher temperatures and thus larger heterotrophic respiration rates (see, e.g., Raich and Potter, 1995), while the long timescales may originate from the carbon dynamics in the extra-tropics, where respiration rates are smaller due to lower temperatures. This hypothesis may be checked by examining Fig. 10d, which shows the contribution from the tropics and the extra-tropics to the land carbon spectrum (Eq. 31). However, as seen, the two peaks arise both in the tropical and in the extra-tropical spectrum, so that one cannot attribute each peak to a particular region. Therefore, this cannot be the explanation.

An alternative hypothesis is that the different peak timescales originate from the very different characteristic timescales of functionally different elements in the land carbon cycle such as leaves, wood, litter and soil. In the following we investigate whether this hypothesis can explain the two-peak structure.

For this purpose, we split the land carbon pools of the MPI-ESM into two groups (see Fig. 11). In the first group are the pools whose dynamics is governed by fast processes such as shedding and decomposition of leaves, thus the pools that respond at short timescales. These are the pools representing non-woody tissues in living vegetation (leaves, fine roots,
sugars, and starches) and the associated litter. In the second group are the pools with dynamics determined by slow processes such as the decomposition of woody plant parts, hence the pools that respond at long timescales. These are the pools representing the wood in stems and coarse roots, the associated litter pools, and the soil carbon (humus).

Now, we separate the land carbon spectrum into contributions arising from each of these two groups. The land carbon response can be described as the sum of the collective responses from the pools with fast and slow dynamics:

\[ \Delta C^{bgc}(t) = \Delta C^{bgc,f}(t) + \Delta C^{bgc,s}(t). \]  

(32)

In the linear response framework, the response of each term to NPP is given by

\[ \int_0^t \chi_{NPP}(t-s)\Delta NPP(s)\,ds \]

\[ = \int_0^t \chi_{NPP}(t-s)\Delta NPP(s)\,ds \]

\[ + \int_0^t \chi_{NPP}(t-s)\Delta NPP(s)\,ds, \]  

(33)

which implies

\[ \chi_{NPP}(t) = \chi_{NPP}^f(t) + \chi_{NPP}^s(t). \]  

(34)

Finally, assuming that each response function in Eq. (34) is described by Eq. (5), we obtain the separation of the land carbon spectrum in terms of the contribution from each pool group:

\[ q_{NPP}(t) = q_{NPP}^f(t) + q_{NPP}^s(t). \]  

(35)

Hence, if our hypothesis is correct, then the peak at short timescales should be explained by \( q_{NPP}^f \) and the peak at long timescales should be explained by \( q_{NPP}^s \).

To proceed with the analysis we now need to obtain the spectra \( q_{NPP}^f \) and \( q_{NPP}^s \). When investigating the tropical and extra-tropical land carbon, we obtained each regional spectrum individually by applying the RFI algorithm to the data from the tropical and extra-tropical responses. In principle one could proceed in the same way to separate contributions from the two pool groups, but, as will become clear below, this approach introduces slight inconsistencies between the separate recoveries that makes a quantitative comparison of this approach introduces slight inconsistencies between the characteristic timescales underlying their dynamics.

Figure 11. Simplified pool scheme of the land carbon cycle in the MPI-ESM (see Appendix A) with pools split into two groups according to the characteristic timescales underlying their dynamics.
Investigation of the contribution from the pools with fast dynamics (non-woody pools) and those with slow dynamics (woody and humus pools) to the land carbon spectrum. The analysis is based on the $2\times$CO$_2$ bgc experiment. (a) Land carbon spectrum $q_{\text{NPP}}$ and its reconstruction via Eq. (35) from the fast and slow components; (b) response function $\chi_{\text{NPP}}$ and its reconstruction via Eq. (34) from the response functions for the fast and slow components; (c) separation of spectrum $q_{\text{NPP}}$ into $q_{f\text{NPP}}$ and $q_{s\text{NPP}}$; (d) separation of response function $\chi_{\text{NPP}}$ into $\chi_{f\text{NPP}}$ and $\chi_{s\text{NPP}}$; (e) separation of $\chi_{\text{NPP}}$ into contributions from the individual pools. For more details, see the text.

More insight into the dynamics of the land carbon can be gained by analyzing the different contributions to the response function $\chi_{\text{NPP}}$ shown in Fig. 12d and e. Figure 12d shows the contribution of the pools with fast dynamics $\chi_{f\text{NPP}}$ and that of the pools with slow dynamics $\chi_{s\text{NPP}}$. We see that $\chi_{f\text{NPP}}$ only dominates the response at times smaller than about 2 years. Further, for times larger than 25 years only $\chi_{s\text{NPP}}$ contributes to the response. In Fig. 12e we further separate the response functions into the contributions from the individual pools, i.e.,

$$\chi_{f\text{NPP}}(t) = \chi_{\text{NPP}}^{\text{nwt}}(t) + \chi_{\text{NPP}}^{\text{nwl}}(t),$$  \hspace{1cm} (38)

$$\chi_{s\text{NPP}}(t) = \chi_{\text{NPP}}^{\text{wt}}(t) + \chi_{\text{NPP}}^{\text{wl}}(t) + \chi_{\text{NPP}}^{\text{h}},$$  \hspace{1cm} (39)

where $\chi_{\text{NPP}}^{\text{nwt}}$ is the response function for the non-woody tissues in living vegetation, $\chi_{\text{NPP}}^{\text{nwl}}$ for non-woody litter, $\chi_{\text{NPP}}^{\text{wt}}$ for woody tissues in living vegetation, $\chi_{\text{NPP}}^{\text{wl}}$ for woody litter, and $\chi_{\text{NPP}}^{\text{h}}$ for the humus pool. This more detailed separation
shows that for long times the humus pool starts to dominate the response, so that at times larger than 100 years it gives the only contribution.

6 Summary, discussion, and outlook

Although the $\gamma$ and $\beta$ values introduced by Friedlingstein et al. (2003) provide a useful framework for model intercomparison, they only characterize the sensitivity of a model for a particular perturbation scenario. Instead, one would like to characterize the sensitivity as an independent property of the carbon cycle. The dependence of $\gamma$ and $\beta$ on the considered scenario arises because of the internal memory of the system, i.e., because of the dependence of the response on past values of the perturbation. When the memory is taken into account, linear response functions arise as natural generalization of the $\gamma$ and $\beta$ sensitivities. However, a fundamental step for applying this generalized framework is to identify the appropriate linear response functions. In Part 1, we developed a method to identify linear response functions from data using only information from an arbitrary perturbation experiment and a control simulation. In that study, the robustness of the method in the presence of noise and nonlinearity was demonstrated in applications to data from perturbation experiments performed with a toy model.

6.1 Generalized land carbon sensitivities in the MPI-ESM

In the present study, we demonstrated that our RFI method can also be employed to derive response functions from C4MIP data. Here, we identified for the MPI-ESM, using data from standard 1% experiments, the land carbon generalized sensitivities $\chi_\gamma$ and $\chi_\beta$, i.e., the linear response functions that generalize the $\gamma$ and $\beta$ sensitivities for land carbon. The robustness of the identified generalized sensitivities was demonstrated by their ability to predict the response from experiments not used for the identification (Sects. 3 and 4). With the aid of additional experiments, we estimated the linear regime that gives the range of forcing strengths for which each generalized sensitivity can predict model responses. For $\chi_\gamma$, results indicate a linear response at least until the end of the 1% experiment, corresponding to temperature perturbations of around 6 K. For $\chi_\beta$, the estimate is for CO2 perturbation strengths up to 100 ppm. In addition, we analyzed different approaches that may be employed to improve the quality of the recovery of the response functions. For $\chi_\gamma$, taking the response from a 2xCO2 experiment demonstrated to give smaller prediction errors for every response evaluated, suggesting that this type of experiment also gives a better recovery. For $\chi_\beta$, the estimated linear regime of only 100 ppm indicates that for larger forcing strengths nonlinearities are present in the response that deteriorate the recovery of $\chi_\beta$. To circumvent such nonlinearities and thus improve the recovery, we identified $\chi_\beta$ by using NPP instead of CO2 as forcing. We found that by this approach an approximately linear response is found over the whole 1% experiment, i.e., until CO2 perturbations of about 850 ppm. This result suggests that nonlinearities in the biogeochemical response of land carbon can to a large extent be explained by the nonlinear relationship between NPP and CO2. This approach of using NPP as forcing instead of CO2 yielded the best recovery for $\chi_\beta$. Evidences for this conclusion are the quality of its prediction and the detailed spectrum it yields for the response.

6.2 Spectrum of land carbon timescales

Obtaining the spectrum of the response is an additional advantage of the RFI method. Most methods in the literature either recover $\chi(t)$ pointwise – and therefore do not give the spectrum – or try to fit it with few exponents without accounting for ill-posedness, which does not give reliable results for the spectrum (see, e.g., the famous example from Lanczos, 1956, p. 272). In the application to the MPI-ESM, obtaining the spectrum has proven advantageous for two reasons. First, it allows one to formally extend the recovery of the response function beyond the time range of the length of the underlying time series. Results from such an extension (Fig. 8a and b) demonstrated that the recovered response function contains information on times reasonably longer than the time series length used for the recovery.

Second, the spectrum gives valuable insight into the internal dynamics of the system. In particular, for our application the spectrum gives the most relevant timescales for the land carbon response on a global or regional level. The spectrum associated with the best recovery of $\chi_\beta$ showed two peak timescales for the global response: one around 4 and another around 100 years (Sect. 5).

To obtain evidence for the robustness of this result, we showed that it is possible to reconstruct the global spectrum from the recovered tropical and extra-tropical spectra (see Fig. 10c), and that similar timescale ranges can be obtained via a Gregory-type approach (see Fig. 9b and c). Further, we demonstrated that the recovered tropical and extra-tropical response functions combine to the identified global response functions, indicating consistency between regional and global recovery (see Fig. 10a and b).

We then proceeded to investigate the reason for the two-peak structure of the spectrum. To this end, we separated the land carbon response into the response from pools with fast dynamics (non-woody vegetation tissues and associated litter) and the response from pools with slow dynamics (woody vegetation tissues, woody litter, and humus). By analyzing the spectrum for each of these responses we showed that the peak at short timescales of the land carbon spectrum arises mostly from the contribution of the pools with fast dynamics, while the peak at long timescales follows closely the contribution from the pools with slow dynamics. This investigation therefore suggests that the two-peak spectrum results from
the different contributions of functionally different elements of the land carbon cycle. Analysis of the response functions showed that the pools with fast dynamics dominate the land carbon response only for times below 2 years. Further, for times larger than 25 years only the pools with slow dynamics contribute to the response, and from 100 years onwards the contribution comes solely from the humus pool.

We remark that results for the spectrum should be always interpreted with care, since deriving the spectrum may be a more complicated problem than deriving the response function. This is partially explained by the degree of ill-posedness of each problem. In deriving the response function from Eq. (3), one is solving a deconvolution problem, which is known to be ill-posed because of the smoothing property of the convolution operator (e.g., Landl et al., 1991; Bertero et al., 1995; Hansen, 2002). On the other hand, by deriving the spectrum from Eqs. (3) and (5), one is solving not only a deconvolution (Eq. 3), but also a type of inverse Laplace transform (to obtain the spectrum from the response function 5), which is known to be extremely ill-posed because of the smoothing property of the Laplace operator (e.g., McWhirter and Pike, 1978; Istratov and Vyvenko, 1999). As a result, deriving \( q(\tau) \) from the data \( \Delta Y(t) \) involves two smoothing operations, namely the Laplace transform and convolution, whereas deriving \( \chi(t) \) from \( \Delta Y(t) \) involves only convolution, so that the problem of finding \( q(\tau) \) may be more ill-posed than that of finding \( \chi(t) \). This difficulty was exemplified by results from Appendices D and E, which discuss cases where the response function can be perfectly recovered but the recovered spectrum is relatively poor.

Another worthwhile comment is that, in comparison to the widely used assumption that the spectrum can be described by only a few exponents (Maier-Reimer and Hasselman, 1987; Enting and Mansbridge, 1987; Enting, 1990; Joos et al., 1996, 2013; Pongratz et al., 2011; Colbourn et al., 2015; Lord et al., 2016), our assumption of a continuous spectrum (ansatz 5) has some advantages. First, by our approach one circumvents the complication of determining the number of exponents. This leads to a linear problem and thereby to a more transparent method (see Part 1, Sect. 3.1). Second, our ansatz better describes the expectation that variables integrated over many different climate zones are composed by a large range of timescales.

In the present investigation we have studied rather idealized simulations where only perturbations in atmospheric CO\(_2\) are acting on the climate system. A possible next step towards the application of our sensitivity analysis to more realistic scenarios could be to consider historical experiments where other perturbations such as land-use change and non-CO\(_2\) greenhouse gases are also applied. To this end, a combination of different response functions should be considered to take separately into account the response of the system to each perturbation (as, e.g., in Bódai et al., 2020). Another possible extension of our study could be to employ response functions to study the spatial dynamics of the carbon cycle. We have shown a simple example of this type of application by looking at the responses for tropics and extra-tropics, but in the literature one also finds applications to study the response latitudinally resolved and even globally

6.3 Outlook

In this study we investigated the generalized \( \gamma \) and \( \beta \) sensitivities that solve the scenario dependence problem noted, e.g., by Gregory et al. (2009) and Arora et al. (2013) to linear order in the perturbation – an approach that can in principle be extended to higher orders (Ruelle, 1998; Lucarini, 2009). By demonstrating how to successfully recover generalized sensitivities, this study paves the way for their future application in studying the dynamics of the combined carbon climate system in different Earth system models. Applying our RFI method, we showed for the MPI-ESM that one can obtain these sensitivities from standard C\(^4\)MIP 1 % simulations. In addition, the estimates for the linear regime obtained by employing the recovered sensitivities to predict additional experiments give a hint at the range of perturbation strengths for which this generalized framework might be valid for other models as well for which data from additional experiments necessary to determine this linear regime are not available. Since the process descriptions of the land carbon cycle are quite similar in different models, it may be assumed that the linear range estimates obtained for MPI-ESM in the present study also apply to other models. Considering the radiative land carbon response, for other models their \( \chi_\gamma \) should thereby also fully characterize the response to temperature up to at least 6 K. As a consequence, in models with temperature responses similar to or weaker than the MPI-ESM, \( \chi_\gamma \) can as for the MPI-ESM be recovered taking the full time series from the 1 % experiment. Analogously, considering the generalized sensitivity \( \chi_\beta \), the experience presented in the present study for the MPI-ESM suggests that also for other models the response to CO\(_2\) perturbations is linear up to 100 ppm. As a consequence, \( \chi_\beta \) can be recovered taking data from the 1 % experiment for the first 30 years. Alternatively, as discussed in Sect. 4, the time range for the recovery of \( \chi_\beta \) can be extended if one takes as forcing NPP instead of CO\(_2\) (third approach investigated in Sect. 4).

For models with NPP responses similar to or weaker than the MPI-ESM, by this approach \( \chi_\beta \) can be recovered taking the full time series from the 1 % experiment. Still, as the relatively successful predictions in Fig. 8b suggest, even if \( \chi_\beta \) is recovered by taking CO\(_2\) as forcing for only 30 years of the 1 % experiment (first approach investigated in Sect. 4), it may still contain sufficient information to predict responses of the model for a time range of 140 years. In the present investigation we have studied rather idealized simulations where only perturbations in atmospheric CO\(_2\) are acting on the climate system. A possible next step towards the application of our sensitivity analysis to more realistic scenarios could be to consider historical experiments where other perturbations such as land-use change and non-CO\(_2\) greenhouse gases are also applied. To this end, a combination of different response functions should be considered to take separately into account the response of the system to each perturbation (as, e.g., in Bódai et al., 2020). Another possible extension of our study could be to employ response functions to study the spatial dynamics of the carbon cycle. We have shown a simple example of this type of application by looking at the responses for tropics and extra-tropics, but in the literature one also finds applications to study the response latitudinally resolved and even globally
at grid-cell level (Thompson and Randerson, 1999; Lucarini et al., 2017).

However, in addition to the carbon cycle sensitivities considered here, our RFI method may be applied to investigate different aspects of climate and the carbon cycle. Ragone et al. (2016) have shown how the linear response framework generalizes the concept of equilibrium climate sensitivity (ECS) and transient climate response (TCR). Originally, ECS is defined as the response of global temperature to an instantaneous doubling of atmospheric CO$_2$ from its pre-industrial value, while TCR is the temperature response to a doubling of CO$_2$ after a 1% per year increase. Within the generalized framework, the ECS and TCR are shown to be only particular values encoded in a linear response function.

Linear response functions can also be useful in studying “committed changes” (Wigley, 2005; Plattner et al., 2008; Jones et al., 2009; Mauritzen and Pincus, 2017). As shown by Ragone et al. (2016), the concept of climate inertia (closely related to committed changes) can be explicitly described within the linear response framework. Since the linear response function describes the delayed response of the system to a perturbation, by deriving this function one also has at hand the information of how the system reacts once the perturbation – for instance CO$_2$ emissions – ceases.

Further, linear response functions can help understanding the concept of “emergent constraints” (Nijssen and Dijkstra, 2018). Recent studies have shown how to obtain from response functions derived from conceptual models emergent constraints for the real Earth system (Cox et al., 2018; Williamson et al., 2019). With the method developed here, in principle such types of analyses may be carried out employing instead response functions derived from Earth system models.

As a result of accounting for the memory of the system, the linear response function gives information on the strength of the response at all internal timescales covered by the time series underlying its recovery and probably even slightly longer (see Fig. 8b). Using our method, in principle one can even compare the spectra of timescales from models to those from observations (e.g., Forney and Rothman, 2012b). The method presented here may also be applied to analyze changes in age and transit time distributions of carbon in different models, since these distributions can be derived directly from linear response functions (Thompson and Randerson, 1999).

In all of the mentioned examples, the generality of the RFI method allows for the derivation of the appropriate linear response functions for any model by taking only data from an arbitrary perturbation experiment and a control experiment. Such generality opens the possibility of combining the linear response framework, which has been gaining increasing attention due its wide applicability in climate science (e.g., Lucarini, 2009; Lucarini and Sarno, 2011; Lucarini et al., 2014, 2017; Ragone et al., 2016; Aengenheyster et al., 2018; Ghil and Lucarini, 2020; Lembo et al., 2020; Bódai et al., 2020), with model intercomparison studies, hopefully leading to a deeper understanding of critical differences encountered across models.

Appendix A: The Max Planck Institute for Meteorology Earth System Model

In this Appendix we give a brief description of the model employed in this study: the Max Planck Institute for Meteorology Earth System Model (MPI-ESM; for more details see Giorgetta et al., 2013). The MPI-ESM consists of the coupled general circulation models ECHAM6 (Stevens et al., 2013) for atmosphere, at T63/1.9° horizontal resolution with 47 vertical levels, and MPIOM (Jungclaus et al., 2013) for ocean, with a nominal resolution of 1.5° with 40 vertical levels. In addition, the MPI-ESM includes the subsystems JSBACH (Reick et al., 2013; Schneck et al., 2013), a land and vegetation model, and the marine biogeochemistry model HAMOCC (Ilyina et al., 2013). JSBACH and HAMOCC describe, respectively, the land and ocean carbon cycle in the MPI-ESM. Thus, of particular interest for our study is the subsystem JSBACH. JSBACH simulates fluxes of energy, water, momentum and CO$_2$ between the land surface and atmosphere. To represent subgrid scale heterogeneity, each grid cell of the land surface is divided into tiles, each tile being associated with a vegetation type (or “plant functional type”). The photosynthesis scheme follows Farquhar et al. (1980) and Collatz et al. (1992). The land carbon structure is divided into three vegetation pools (living tissues, carbohydrate and starch storage, and wood), four aboveground and belowground pools for litter from woody and non-woody parts and a pool for soil carbon (humus). In addition, JSBACH includes a dynamic vegetation scheme that allows for simulating changes in vegetation cover driven by climate.

Appendix B: Generalization of climate-carbon cycle sensitivities

In this Appendix we show that linear response functions indeed generalize Friedlingstein $\alpha$–$\beta$–$\gamma$ sensitivities. We explain this by taking the $\beta$ sensitivity of land carbon uptake as an example. The calculation of $\beta$ is based on an experiment where the CO$_2$ rise acts only biogeochemically, i.e., concerning the land carbon via the photosynthesis of plants. Calling $\Delta C_{\text{bgs}}(t)$ the difference in land carbon between the perturbed and the control simulation, $\beta$ is defined as

$$\beta(t) = \frac{\Delta C_{\text{bgs}}(t)}{\Delta C_{\text{atm}}(t)}, \quad \Delta C_{\text{atm}}(t) = C_{\text{atm}}^0(1.01^t - 1), \quad (B1)$$

where $t$ is the time in years elapsed since the perturbation was switched on, and $\Delta C_{\text{atm}}(t)$ is the change in CO$_2$ concentration when increasing atmospheric CO$_2$ each year by 1% starting from its pre-industrial value $C_{\text{atm}}^0$ of the control
simulation. In the framework of linear response, one can understand \( \Delta C_{\text{atm}}(t) \) as perturbation and \( \Delta C^{\text{bg}}(t) \) as response, so that the response formula reads

\[
\Delta C^{\text{bg}}(t) = \int_0^t \chi_\beta(t-s)\Delta C_{\text{atm}}(s)\,ds. \tag{B2}
\]

This equation defines \( \chi_\beta(t) \) as the linear response function describing the biogeochemical response of land carbon to any type of CO\(_2\) perturbation \( \Delta C_{\text{atm}}(t) \), as long as the perturbation is sufficiently weak. Employing in particular the percent perturbation from Eq. (B1), \( \beta(t) \) is thus obtained from the linear response function \( \chi_\beta(t) \) as

\[
\beta(t) = \frac{1}{\Delta C_{\text{atm}}(t)} \int_0^t \chi_\beta(t-s)\Delta C_{\text{atm}}(s)\,ds. \tag{B3}
\]

In this way, \( \chi_\beta(t) \) can be understood as a generalization of \( \beta(t) \) that gives not only the response to percent-type perturbations, but also to other perturbations. Accordingly, \( \chi_\beta(t) \) characterizes system properties independent of the type of perturbation, in contrast to \( \beta(t) \).

**Appendix C: Monotonicity of \( \chi_\beta(t) \)**

In this Appendix it is shown that the response function \( \chi_\beta(t) \) is monotonic, as claimed in Sect. 2.1. The argument here is actually more general, namely that the response function to changes in the input of the system (for land carbon, the net primary production) is monotonic, as claimed in Sect. 2.1. The argument here is actually more general, namely that the response function to changes in the input of the system (for land carbon, the net primary production) is monotonic. Since \( \chi_\beta(t) \) is related to \( \chi_{\text{NPP}}(t) \) by Eq. (21), the monotonicity property transfers to \( \chi_\beta(t) \).

Let the linear response of land carbon be described by Eq. (17):

\[
\Delta C^{\text{bg}}(t) = \int_0^t \chi_{\text{NPP}}(t-s)\Delta \text{NPP}(s)\,ds, \tag{C1}
\]

where for simplicity we assume that \( \eta(t) \) is small, so that it can be neglected. If NPP is a Dirac delta function \( \Delta \text{NPP}(t) = \delta(t) \), then the response is given by \( \Delta C^{\text{bg}}(t) = \chi_{\text{NPP}}(t) \). Therefore we can interpret the response function \( \chi_{\text{NPP}}(t) \) as follows: if a certain number of carbon atoms enter the biosphere at time \( t = 0 \), the response function \( \chi_{\text{NPP}}(t) \) gives the fraction of these atoms still left in the biosphere at time \( t \).

Let \( p(t)\,dt \) be the probability that an atom that entered the system at time \( t = 0 \) will leave it at time \( t \). Then

\[
P(t) := \int_0^t p(s)\,ds \tag{C2}
\]

is the probability that an atom that entered the system at time \( t = 0 \) will leave the system until time \( t \). Hence from the interpretation of \( \chi_{\text{NPP}}(t) \) above,

\[
P(t) = 1 - \chi_{\text{NPP}}(t). \tag{C3}
\]

From Eqs. (C2) and (C3) it follows that

\[
p(t) = -\frac{d}{dt} \chi_{\text{NPP}}(t). \tag{C4}
\]

However, since the probability density function \( p(t) \geq 0 \, \forall t \), then \( \frac{d}{dt} \chi_{\text{NPP}}(t) \leq 0 \, \forall t \), i.e., \( \chi_{\text{NPP}}(t) \) decays monotonically towards zero. Therefore, because \( \chi_\beta(t) \) is simply a scaling of \( \chi_{\text{NPP}}(t) \) given by Eq. (21), \( \chi_\beta(t) \) also decays monotonically towards zero.

**Appendix D: Derivation of spectrum and \( \chi(t) \) when the response contains timescales much longer or much shorter than the timescales covered by data**

Timescales much longer or much shorter than the timescales covered by data cannot be correctly recovered in the spectrum. Nevertheless, in this Appendix we show that the wrong recovery of these extreme timescales does not strongly affect the recovery of \( \chi(t) \). These considerations add to the footnote remark in Sect. 5 where we claim that such extreme timescales can be safely ignored.

First, we consider the case where the response has timescales much longer than those covered by data. Let \( \chi \) at time \( T \) be given by

\[
\chi(T) = \int_{-\infty}^{\infty} q(\tau) e^{-T/\tau} d\log_{10}\tau. \tag{D1}
\]

Let \( T \) be the time series length and assume that \( q(\tau) \) has significant contributions at timescales \( \tau \geq \tau_L \) with \( \tau_L \gg T \). Then (D1) can be written as

\[
\chi(T) \approx \int_{-\infty}^{\log_{10}\tau_L} q(\tau) e^{-T/\tau} d\log_{10}\tau + \int_{\log_{10}\tau_L}^{\infty} q(\tau) d\log_{10}\tau, \tag{D2}
\]

where \( e^{-T/\tau} \approx 1 \) was used in the second integral because \( \tau_L \gg T \). Thereby the second term in the right-hand side of (D2) is just a constant offset

\[
\int_{\log_{10}\tau_L}^{\infty} q(\tau) d\log_{10}\tau = k, \quad k \text{ constant.} \tag{D3}
\]

Hence, for internal timescales much longer than the time series length \( T \), the correct recovery of the individual \( q(\tau) \) values is not relevant for the derivation of \( \chi(t) \), as long as those
values combine to the correct offset in Eq. (D3). Note that because this argument is based on the condition \( \tau_L \gg T \), it applies not only to \( \chi(T) \), but also to all \( \chi(t) \), \( t < T \).

Now, we consider the case where the response has timescales much smaller than those covered by data. Let \( t = i \Delta t \), where \( \Delta t \) is the time step and \( i \in \mathbb{N} \). If \( q(\tau) \) has significant contributions at timescales \( \tau \leq \tau_S \) with \( \tau_S \ll \Delta t \), then for \( i > 0 \) Eq. (5) can be written as

\[
\chi(i \Delta t) \approx \int_{\log_{10} \tau_S}^{\infty} q(\tau) e^{-i \Delta t / \tau} d\log_{10} \tau, \quad (D4)
\]

where \( e^{-i \Delta t / \tau} \approx 0 \) was used for \( \tau < \tau_S \) because \( \tau_S \ll \Delta t \). As a result, values of \( q(\tau) \) are irrelevant to \( \chi(t) \) for almost every \( i \). The only exception is \( i = 0 \), where one has

\[
\chi(0) = \int_{-\infty}^{\infty} q(\tau) d\log_{10} \tau. \quad (D5)
\]

Hence, for timescales much shorter than the time step \( \Delta t \), the correct recovery of the individual \( q(\tau) \) values is not relevant for the derivation of \( \chi(t) \) as long as those values combine with the other recovered values of \( q(\tau) \) to the correct \( \chi(0) \) in Eq. (D5). As shown by Eq. (D4), if they combine to the wrong value, only the recovery of \( \chi(0) \) is affected.

Therefore, in principle \( \chi(t) \) can also be correctly recovered when the response contains much longer and much shorter timescales than those covered by data, as long as the recovered \( q(\tau) \) values at these extreme timescales combine to the correct values of the offset in Eq. (D3) and \( \chi(0) \) in Eq. (D5). In Fig. D1 we show an example of recovery of the spectrum and response function in such a case. For the recovery we took data with SNR = 6 \times 10^4 from the 1% experiment with our toy model (see Part 1). As seen, the spectrum can only be partially recovered (Fig. D1a). The recovery wrongly estimates spectral contributions at timescales longer and shorter than those covered by data, i.e., timescales larger than the time series length \( T = 140 \) and smaller than the time step \( \Delta t = 1 \). In addition, the existence of such spectral contributions at timescales not covered by data seems to also deteriorate the recovery of the spectrum at the timescales actually covered by data: in the region \( 1 < \tau < 140 \), despite the high SNR the recovered spectrum matches the true spectrum only partially. This is probably a compensation effect where wrong information shows up in the recovered spectrum to compensate missing information on the response function. For instance, to obtain the correct \( \chi(0) \), only Eq. (D5) is needed but not the correct recovery of all timescales. The same goes for obtaining the correct offset: only Eq. (D3) is needed but not the correct recovery of all timescales from \( \tau_L \) onwards.

Figure D1b shows the quality of the recovery of the response function \( \chi(t) \). The recovered \( q(\tau) \) values at long timescales, although individually wrong, combine to the correct offset in Eq. (D3); the “height” of the recovered response function matches almost perfectly that of the true response function (compare, e.g., the value at \( t = 140 \) for the true and recovered response function). On the other hand, \( \chi(0) \) is not perfectly recovered (compare the difference at \( t = 0 \) between the true and recovered response functions), meaning that the sum in Eq. (D5) is incorrect. Nevertheless, the recovered value is still reasonably close to the true value. Except for this small error at \( \chi(0) \), the overall recovery of the response function is almost perfect.

Therefore, as claimed in Sect. 5, this numerical example shows that even though very long and very short timescales cannot be correctly recovered in the spectrum, they do not strongly influence the recovery of \( \chi(t) \). This is because they only influence the offset in Eq. (D3) and \( \chi(0) \) in Eq. (D5), and those two values seem to be reasonably well recovered numerically.

Appendix E: Recovering a discrete spectrum \( q(\tau) \)

This Appendix gives numerical evidence for the claim in Sect. 6 that although the RFI method assumes that the response has a continuous spectrum of many timescales, for sufficiently good signal-to-noise ratio the recovered continuous spectrum may also give a reasonable approximation to an underlying discrete spectrum of only few timescales.

Before we give numerical examples, one must first understand the limitations of the recovery of the spectrum. As explained in Part 1, the spectrum \( q(\tau) \) can only be completely recovered (for sufficiently high SNR) if it is dominated by the first components of expansion (Eq. 6). By Hansen’s observation (Hansen, 1989, 1990, see Part 1), this means that the spectrum must be dominated by low frequencies; i.e., it must be to some extent smooth. However, an underlying discrete spectrum implies a spectrum that is instead given by “spikes” in the timescale domain. Such “spikes” can only be described by high-frequency components of Eq. (6). Therefore, a discrete spectrum can be only partially recovered. To obtain a sufficiently good recovery, the solution (Eq. 6) must contain many components. Hence, the data must have a sufficiently high signal-to-noise ratio. The explanation for this conclusion is the following: if many components in Eq. (6) must be recovered, the regularization parameter must be small; but a small regularization parameter requires a small noise level (see Theorem 3.3.1 in Groetsch, 1984).

With this in mind, we show in Figs. E1–E9 that at least smooth approximations to an underlying discrete spectrum can be obtained. For the results we took data with SNR \( \sim O(10^6) - O(10^5) \) from different experiments performed with the toy model described in Part 1. Since the aim is to recover discrete spectra, a larger number of timescales \( M \) gives a bet-
Figure D1. Recovery of spectrum and $\chi(t)$ taking a true spectrum with contributions at timescales much longer and much shorter than the timescales covered by data. For the recovery, data with SNR = $6 \times 10^4$ from the 1% experiment with the toy model (see Part 1) was taken (time series length $T = 140$ and time step $\Delta t = 1$). RFI parameters are taken as in Part 1 except for $M = 140$. The recovered spectrum matches only partially the true spectrum. Nevertheless, the response function $\chi(t)$ is almost perfectly recovered.

Figure E1. Spectrum $q_\lambda$ and response function $\chi(t)$ recovered from a 1% experiment performed with the toy model described in Part 1 taking an underlying discrete spectrum with one timescale $\tau = 37$. The data were taken with SNR $\sim O(10^4) - O(10^5)$.

Figure E2. Spectrum $q_\lambda$ and response function $\chi(t)$ recovered from a 1% experiment performed with the toy model described in Part 1 taking an underlying discrete spectrum with two timescales $\tau = 7$ and $\tau = 100$. The data were taken with SNR $\sim O(10^4) - O(10^5)$.

ter resolution. Therefore, we take $M = 140$. All other RFI parameters are taken according to Part 1. Also, monotonicity needed not to be taken into account (step 6 of Fig. 1 in Part 1).

Figures E1–E6 show results for taking data from a 1% experiment and Figs. E7–E9 from a $2 \times f_0$ experiment. We start with one timescale $\tau = 37$ (Fig. E1). As expected, the spike cannot be perfectly recovered, but the recovery gives a smooth approximation to it, with the peak coinciding approximately with the “true” value. On the other hand, the response function is almost perfectly recovered. This is a result of the ill-posedness of Eq. (5): in the same way that high frequen-
Figure E3. Spectrum $q_\lambda$ and response function $\chi(t)$ recovered from a 1% experiment performed with the toy model described in Part 1 taking an underlying discrete spectrum with two timescales $\tau = 7$ and $\tau = 37$. The data were taken with SNR $\sim O(10^4) - O(10^5)$.

Figure E4. Spectrum $q_\lambda$ and response function $\chi(t)$ recovered from a 1% experiment performed with the toy model described in Part 1 taking an underlying discrete spectrum with two timescales $\tau = 37$ and $\tau = 100$. The data were taken with SNR $\sim O(10^4) - O(10^5)$.

Figure E5. Spectrum $q_\lambda$ and response function $\chi(t)$ recovered from a 1% experiment performed with the toy model described in Part 1 taking an underlying discrete spectrum with three timescales $\tau = 7$, $\tau = 37$, and $\tau = 100$. The data were taken with SNR $\sim O(10^4) - O(10^5)$.

cies of the spectrum are suppressed in the data by Eq. (3), they are also suppressed in the response function by Eq. (5) (see Groetsch, 1984, Sect. 1.1). Therefore, both the true spectrum and its smooth recovery result in practically the same response function.

In Fig. E2, the true spectrum has two timescales, this time at $\tau = 7$ and $\tau = 100$. Similarly to Fig. E1, the timescales are recovered by a smooth approximation with peaks approximately at the true values. Also similarly to Fig. E1, the response function is almost perfectly recovered. A similar result is obtained if we take timescales that are a bit closer together, as seen in Fig. E3 ($\tau = 7$ and $\tau = 37$). Nevertheless, now the peak for the longer timescale is a worse approximation, and there is a slightly pronounced negative peak that does not reflect the true spectrum.
Figure E6. Spectrum \( q_\lambda \) and response function \( \chi(t) \) recovered from a 1% experiment performed with the toy model described in Part 1 taking an underlying discrete spectrum with four timescales \( \tau = 1, \tau = 7, \tau = 37, \) and \( \tau = 100. \) The data were taken with SNR \( \sim O(10^4) - O(10^5). \)

Figure E7. Spectrum \( q_\lambda \) and response function \( \chi(t) \) recovered from a 2 \( \times \) \( f_0 \) experiment performed with the toy model described in Part 1 taking an underlying discrete spectrum with four timescales \( \tau = 1, \tau = 7, \tau = 37, \) and \( \tau = 100. \) The data were taken with SNR \( \sim O(10^4) - O(10^5). \)

Figure E8. Spectrum \( q_\lambda \) and response function \( \chi(t) \) recovered from a 2 \( \times \) \( f_0 \) experiment performed with the toy model described in Part 1 taking an underlying discrete spectrum with four timescales \( \tau = 1, \tau = 7, \tau = 37, \) and \( \tau = 228. \) The data were taken with SNR \( \sim O(10^4) - O(10^5). \).

In Fig. E4, we take instead timescales \( \tau = 37 \) and \( \tau = 100. \) Here, the resolution is not sufficiently high for a recovery of each timescale separately. Instead, the recovered spectrum shows only one mode that spans both spikes. Once more the response function can be almost perfectly recovered. Taking the three timescales \( \tau = 7, \tau = 37, \) and \( \tau = 100 \) (Fig. E5), the smooth recovery shows only two modes: one at \( \tau = 7 \) with peak almost coinciding with the true value, and another with peak in between \( \tau = 37 \) and \( \tau = 100. \) If one in addition considers a fourth timescale \( \tau = 1 \) (Fig. E6), once more the recovery shows only two modes. However, now the mode at
shorter timescales displays a longer tail that spans both $\tau = 7$ and $\tau = 1$.

The situation changes when we take for the recovery the $2 \times \text{CO}_2$ experiment. According to the Laplace transform analysis in Sect. 3, data from this experiment should give more information on small timescales. Figure E7 shows that this is indeed the case: in contrast to the recovery from Fig. E6, now the timescale $\tau = 1$ is also recovered. On the other hand, now there are two small negative peaks that do not reflect information from the true spectrum. Also, the resolution is not sufficiently good to recover separately the two peaks at long timescales. However, if the longest timescale is increased from $\tau = 100$ to $\tau = 228$ (Fig. E8), a small peak can be seen around this timescale. In addition, now the peak at $\tau = 37$ matches slightly better the true value. In Fig. E9 we add another timescale, now at $\tau = 518$. We see that although this timescale cannot be recovered separately from $\tau = 228$, the peak at long timescales is more pronounced. This is in contrast with the fact that the time series used for the recovery reaches only $t = 140$, indicating that the method can recover information on timescales even longer than the time series length. This is in agreement with the conclusions from Sect. 4, where in one case $\chi_\beta(t)$ was recovered from a time series with only 30 years but could recover responses for $t = 140$ years (see Fig. 8b).
