Interactive Discussion

into a leading wave packet and trailing wave-train qualitatively in agreement with the predictions of Grimshaw and Helfrich (2008). However, the leading packet cannot be completely separated from the trailing tail on the scale of even the largest experiments.

The geostrophic state oscillates at the inertial frequency, in agreement with the results of Kuo and Polvani (1997). Shock-like bore fronts do not form during the geostrophic adjustment, since the model resolution is sufficient to consider both the large scales influenced by rotation and shorter scales dominated by non hydrostatic effects (despite initial conditions matching breaking cases seen in Kuo and Polvani, 1997).

The Rossby number (Ro) can be varied by modifying either the length scale of the initial disturbance or the rotation rate. Both choices will alter the proportion of energy that remains in the geostrophic state and that propagates away. Moreover, the amplitude of the inertial oscillations that the geostrophic state undergoes will also change. We find qualitatively different behaviour of the leading packet for $Ro = 1.25$ and 0.75 . We investigate the effects of polarity of the initial disturbance and find that, as expected, the geostrophic state is unaffected by polarity. We find that at high rotation rates the wave packet behaviour is largely unchanged by changes in polarity. We subsequently investigate the regime of weaker rotation effects. We find that while there is evidence of a wave packet emerging from the undular bore, though the packet never completely separates from the tail, even at higher rotation rates. We illustrate that the spectrum of the vertically averaged kinetic energy is fundamentally different in the rotating case, thereby providing a diagnostic in the rotation modified cases.

2 Methods

For the following numerical simulations, the full set of stratified Euler equations for an incompressible fluid were used, though no span-wise variations were considered. Rotation was incorporated using an f-plane approximation and the non-traditional terms were dropped, see Gerkema et al. (2008) for a review of this process. The

x axis is taken as parallel to the flat ocean bottom with the z axis pointing upward (\hat{k} is the upward directed unit vector). The Euler equations for velocity $\mathbf{u} = [u(x, z, t), v(x, z, t), w(x, z, t)]$, density $\rho(x, z, t)$ and pressure $P(x, z, t)$ are,

$$\frac{D\mathbf{u}}{Dt} + (-fv, fu, 0) = -\nabla P - \rho'g\hat{k} + \nu\nabla^2\mathbf{u}, \quad (1)$$

$$\nabla \cdot \mathbf{u} = 0, \quad (2)$$

$$\frac{D\rho}{Dt} = 0. \quad (3)$$

In accordance with convention we have divided the momentum equation by the constant reference density ρ_0 and absorbed the hydrostatic pressure into the pressure P . We make the Boussinesq approximation for density and write $\rho = \rho_0(1 + \bar{\rho}(z) + \rho'(x, z, t))$ where $\bar{\rho}$ is the background density profile and ρ' is considered a small perturbation. Due to our interest in the wave dynamics in the main water column, as opposed to details of the boundary layer dynamics, we impose free slip boundary conditions at the top and bottom of our domain this will also ensure that the boundary layer does not play a significant role in the simulations on which we report. The walls allow us to mimic a lock-release setup that is used to create waves in many laboratory setups (Carr and Davies, 2006; Grue et al., 2000; Helfrich and Melville, 2006). We have elected to neglect the span-wise dimension (y), as the lab results in Grimshaw et al. (2013) were performed away from any side boundaries and they elected to neglect any curvature from the waves created.

In the following set of experiments the two dimensionless numbers which are dynamically important are the Rossby number and the Reynolds number. The Rossby number is defined as $Ro = \frac{U}{fL}$ where U is the typical wave speed, L is the typical length scale and f is the rotation rate. This reflects a ratio of the inertia term to the Coriolis force term. When the Coriolis force dominates, the fluid can reach a balance between the rotation and pressure terms, i.e., geostrophic balance. The Reynolds number is given as $Re = \frac{UL}{\nu}$, where U and L are the same as for Ro and ν is the kinematic viscosity. In

isopycnal displacement η .

$$\rho(x, z, t = 0) = \bar{\rho}(x, z - \eta) = 0.005 \tanh\left(\frac{z - 0.3 - \eta}{0.01}\right),$$

$$\eta = \pm 0.05 \exp\left[-\left(\frac{x}{w}\right)^8\right],$$

where w is the half width of the initial perturbation and the sign changes correspond to changes in jump orientation.

3 Results

In this section we present the results of multiple numerical simulations. The primary way in which the parameters were modified was by changing either the initial width of the perturbation or by changing the rotation rate. Using the initial width as the typical length scale, $L = w$, we are thus varying the Rossby number. The resulting values of the dimensionless parameter are shown in Table 1. Across all the cases, the depth does not change, and hence neither does the two-layer linear long wave speed

$U = \sqrt{g \frac{\Delta\rho}{\rho_0} \frac{H_1 H_2}{H_1 + H_2}} = 0.0858 \text{ m s}^{-1}$ where $g = 9.81 \text{ m s}^{-2}$, $\Delta\rho = 0.01$, $\rho_0 = 1$, $H_1 = 0.3 \text{ m}$ and $H_2 = 0.1 \text{ m}$; this implies that there are two readily accessible ways to create a situation with the same Rossby number. Using the same wave speed and length scales as for the Rossby number, the corresponding Reynolds numbers are presented in Table 2; the kinematic viscosity was the same for all simulations, $\nu = 1e^{-6} \text{ m}^2 \text{ s}^{-1}$. It is also possible to define a Reynolds number based on the channel depth, $L = 0.4 \text{ m}$, providing a corresponding $Re = 3.43 \times 10^5$; this would be the same for all cases since domain depth does not change. Several additional experiments were carried out changing the initial wave amplitude which results in different “nonlinearity” parameters. For the initial amplitude of $\eta_0 = 0.05 \text{ m}$ and $H_0 = 0.3 \text{ m}$ we have $\alpha = 0.1667$. For the cases where amplitude is halved and quartered corresponding alpha values are $\alpha = 0.0833$ and 0.0416 .

Interactive Discussion

The initial value of $\alpha = 0.1667$ allows for an easy comparison to many of the figures in Kuo and Polvani (1997) which are based on a value of 0.1.

In addition to the simulations above, another set of simulations were performed using the opposite polarity of the initial disturbance. These opposite polarity simulations correspond exactly to the cases seen in Table 1 the only difference being the sign in the isopycnal displacement used in the initial conditions.

Several simulations were also performed on an extra-long tank to investigate the long-time results of adjustment. For these simulations the tank length was $L = 260\text{m}$ and the number of horizontal grid points was increased to 16384, providing a 1.58cm resolution. The vertical height and grid points were kept the same from the smaller case.

Unless otherwise stated the following scaling is used for all figures: $T = 1/f$, $L_z = Lz$ and $L_x = Ro_r$, where $Ro_r = \frac{U}{f}$ is the Rossby radius of deformation and $Lz = 0.4\text{m}$ is the depth of the tank. For kinetic energy, we scale by the maximum kinetic energy. For the convenience of experimentalists, we report both physical and dimensionless time in the figure captions.

3.1 Non-rotating cases

We begin by reproducing the results for the adjustment problem without rotation. The solution to this problem is well known, and yields either a rank ordered train of solitary waves, or an undular bore forming from the initial disturbance, depending upon the polarity of the initial disturbance. The two cases are shown in Fig. 1. Since there is no rotation, the advective time-scale was chosen to nondimensionalize time, $T = L/U$ (the initial width $w = \frac{1}{2}w_0$ was chosen for the typical length-scale). The stark difference between these cases is readily apparent in both types of plots. The solutions to this problem have already been extensively investigated, and as such we will forgo a detailed discussion here however this behaviour will be used to compare later results.

Interactive Discussion

3.2 General evolution

Comparing the value of our Rossby numbers to those discussed in Grimshaw et al., we find that their case with a rotation rate of 0.105s^{-1} had a corresponding Rossby number of 0.667; thus, we use the $f = f_0$ and $w = w_0$ case as our baseline as it has $Ro = 0.5$ which is in the same regime as their number. Snapshots of the time evolution for this case are provided in Fig. 2.

Observing the structure that appears throughout the time series, we argue that these waves closely resemble a modulated wave packet as presented in Grimshaw et al. (1998) instead of the rotation modified bore seen in Kuo and Polvani (1997). When comparing to the work done by Kuo and Polvani we first note that for our simulations the nonlinear parameter is quite small at $\alpha \approx 0.166$, however their work suggests that even for this small value and smooth initial condition breaking will still occur. The present simulations were carried out with the full set of Euler equations. As such the dispersion that is neglected in the shallow water equations used by Kuo and Polvani becomes important when the wave front steepens. Dispersion breaks the front down into a train of smaller waves and eliminates shock formation. In addition to the change in steepening dynamics, the initially tightly packed waves disperse over time, yet are observed to remain bound together. For this reason we find that the modulated wave packet is a better description for these dynamics.

While the base case of Fig. 2 allows us to easily compare with the results from the LEGI-Coriolis tank with its relatively high rotation rate, in order to compare to what is observable in coastal waters or large lakes, we must consider lower rotation rates. While still being constrained by the size of our extended tank, it was decided to focus on a half and a quarter of the original rotation rate. Figure 3 shows space–time plots of the vertically integrated kinetic energy for these three rotation rates, with the initial width held the same at $w = w_0$. Figure 3a corresponds to case the base case in Fig. 2, while Fig. 3b to $f = \frac{1}{2}f_0$, and Fig. 3c to $f = \frac{1}{4}f_0$. Comparing to Table 1 we see that these cases have $Ro = \frac{1}{2}$, $Ro = 1$ and $Ro = 2$ respectively. In all cases, we can easily identify

the geostrophic state that forms from the initialization near the left hand boundary of the model tank and observe that it oscillates, or pulsates, in time. This is in qualitative agreement with the results from Kuo and Polvani. These pulses are particularly evident in Fig. 3a and b. Comparing the three plots we see that with the decrease in rotation rate we shift the location where, and the time when, the most energetic waves are ejected from the pulsating, geostrophic region. In Fig. 3c the kinetic energy is ejected almost immediately, and by the time the second pulse is visible in the geostrophic region the wave packet is well away from the left boundary. As the wave propagates away, it develops a clear wave packet structure which can be easily identified in the space–time plots. In Fig. 3b we see that the strongest kinetic energy propagates away from the second half of the initial pulse, but also develops a packet structure as it moves away from the geostrophic region. Differences arise when we look at Fig. 3a, which has the highest rotation rate, where a small packet is generated however it is forms from the second pulse. Key to note for this case is that by $t = 286\text{ s}$ (30) the kinetic energy stops reaching a significant level within the packet. As expected, reducing the rotation rate leads to a weaker geostrophic state and more energy in the initial pulse of kinetic energy. Also note that from Fig. 3a and b there is evidence of waves being continuously ejected from the geostrophic state, even for late times in the simulation.

3.3 Geostrophic state

In the rotation modified adjustment problem there are two dominant features, the geostrophic state that is leftover from the initial conditions and the train of Poincaré waves which carries energy away from it. For this section we will focus on the dynamics, and changes, of the geostrophic state.

Figure 4 shows space–time plots of vertically integrated kinetic energy for five cases of different initial widths where the rotation rate has been held constant at $f = f_0$. These cases have Rossby numbers 2, 1, $\frac{1}{2}$, $\frac{1}{4}$ and $\frac{1}{8}$ for Fig. 4a–e respectively. This figure extends the trend seen in Fig. 3 where in this case increasing the initial width modifies the temporal phase of the geostrophic state’s oscillation that leads the wave packet

Interactive Discussion

generation. In particular, the generation occurs during the onset of the first pulse in Fig. 4a and shifts to the middle of the fourth pulse in Fig. 4e. We can also note from this figure that as the initial width is increased, more energy is trapped in the geostrophic state, so that in Fig. 4e almost no energy is ejected via the packet. To further investigate the geostrophic state (shown as the blue dashed line in Fig. 4), the vertically integrated kinetic energy was extracted from this point and is shown separately in Fig. 5a with different colours corresponding to the different cases. It is important to remember that the rotation rate is constant for all of these cases and so inertial oscillations should have the same period. From the plots, we see that the first oscillation appears in roughly the same place for all the cases, but after that there appears to be some phase shifting. However, the $\frac{1}{2}w_0$ and $\frac{1}{4}w_0$ cases are always in phase. Other than the $w = 2w_0$ and $w = 4w_0$ case, the rest of the cases eventually reach a stationary state (or in other words oscillations are too small to be seen on the scale of the graph). The $2w_0$ case looks as if it is in the process of reaching its stationary state, but the $4w_0$ case looks as if the oscillations have reached a constant size and do not seem to decrease. From these results the conclusion is that the $w = w_0$ case appears to settle into the most energetic stationary state. Figure 5b shows the spectral power of the respective time series which clearly shows that all the cases have a strong spike in power around the inertial frequency confirming the results from Kuo and Polvani (1997).

We next consider the time evolution of the proportion of total kinetic energy inside of the geostrophic state to that outside, this is shown in Fig. 6. In this figure we have the same cases as in Fig. 5, $f = f_0$, but separated into their own plots (the panels descend from smallest initial width, $w = \frac{1}{4}w_0$ in Fig. 6a to largest, $w = 4w_0$ in Fig. 6e). The red line is the energy outside the geostrophic state while blue corresponds to that inside. Some immediate features are apparent from the figure: for small initial width, Fig. 6a there is more energy outside of the geostrophic state starting from an early time. The opposite is true for the large case, Fig. 6e, where all the energy is located inside the state and very little outside. In the three intermediate cases we see that there is roughly

Interactive Discussion

shift in phase of the ejected wave packet. The packet is ejected from the front of the first pulse in the $Ro = 1.25$ case while in the $Ro = 0.75$ case the packet originates at the back of the first pulse (almost at the front of the second pulse), this was also seen in Fig. 3 when rotation rate was changed. The second feature is that the geostrophic state is significantly wider and stronger in the $Ro = 0.75$ case. This is consistent with the idea that the Coriolis force is stronger and can trap more energy in the geostrophic state. The last feature worth noting is that in the $Ro = 0.75$ case, there is much more spreading of the wave packet as it travels through the tank. The results from this figure support the evidence seen in Fig. 4 where crossing from below to above one Rossby number corresponds to a change in the dynamics.

3.5 Polarity effects

From the standard KdV theory there is a qualitative difference in the types of waves that are generated from an initial disturbance with negative polarity (a wave of depression) compared to one with a positive polarity (a wave of elevation). In particular, disturbances with negative polarity will yield a rank ordered solitary wave train while those with a positive polarity will yield an undular bore. To investigate this effect for this more general rotation modified adjustment problem we simulated all of the cases from Table 1 a second time with the polarity of the initial conditions reversed.

Figure 9 provides an outline of the time evolution of density for two cases, where their initial polarity is the only difference. The base case of $w = w_0$ and $f = f_0$ is shown. The left column corresponds to starting with an initial wave of depression, while the right column corresponds to an initial wave of elevation. Figure 9a and b are taken at $t = 75$ s (5.25), Fig. 9c and d at $t = 300$ s (21) and Fig. 9e and f at $t = 525$ s (36.75). From these snapshots the only difference that appears to occur is that the waves created are of the opposite polarity, and other than this the two packets look almost identical. More differences are apparent from the space–time plot in Fig. 10 which shows the vertically integrated kinetic energy; from these plots we can see that the positive polarity case Fig. 10b contains more kinetic energy in both the geostrophic

rotation rates is a result of the geostrophic state capturing more energy, resulting in smaller amplitude waves being ejected and thus decreasing the effect of nonlinearity.

A natural question to ask is whether the effects of rotation are clearly reflected in the spectrum of the waves, particularly for the lower rotation rates. Figure 14 shows the spectra of the two polarity cases for two different rotation rates, one low ($f = \frac{1}{8}f_0$), Fig. 14a, and one high ($f = 2f_0$), Fig. 14b; they correspond to Rossby numbers $Ro = 8$ and $Ro = \frac{1}{2}$ respectively. It should be clear from Fig. 14a that in this low rotation case the spectra are not entirely similar. While the positive polarity case matches the first spike in wave-number at ≈ 10 the negative case quickly drops off in power, while the positive cases exhibits several spikes at smaller values of the wave-number. The picture changes dramatically in the high case. In this case, other than a slight phase shift, the spectra are almost identical. The spikes in spectra occur at the same wave-number and are of the same order. This result provides further evidence supporting the claim we have made previously that as we increase the rotation rate, starting from two different polarities, the dynamics collapse to a common result.

To investigate the transition from distinct to uniform dynamics, we examined at the differences in spectra of the ejected waves for the low rotation rate from the previous figure and the case of no rotation. This is presented in Fig. 15. Figure 15a corresponds an initial wave of elevation while Fig. 15b to one of depression. In the case of initial elevation, we can see that when rotation is introduced we increase the power at specific wave-numbers. A similar observation can be made based on panel Fig. 15b, in which the Gaussian-like profile typical of a solitary wave is destroyed by rotation, in favour of peaks at specific wave-numbers. These results suggest that a spectral analysis will reveal the results of rotation equally well for both polarities. This is important since the solitary wave case (in the absence of rotation) can be described quite succinctly, but the unduly bore spreads spatially with increasing time.

4 Conclusions

In this paper we have taken a systematic approach to the classical rotation-modified stratified adjustment problem. In contrast to what was presented in Kuo and Polvani (1997) we have shown that by using the fully nonlinear Euler equations the waves that are ejected from the geostrophic state do not steepen to a shock. By mapping out the parameter space we have shown that, as expected, the Rossby number is the controlling variable for the dynamics in this problem; when the Rossby number is above one we have that a wave packet is ejected from the first inertial wave pulse of the geostrophic state and does not disperse much as it propagates through the tank. In the cases when Rossby number is less than one, the packet is ejected from a later pulse (smaller Rossby numbers corresponding to later pulses) and disperses as it moves through the tank. We characterized the similarities and differences in the dynamics for cases when the same Rossby number is achieved by different means. We found that for the same Rossby number the dynamics of the geostrophic state are nearly identical, and there are some small differences between the wave-trains but the dynamics are very similar. Our results also show that the oscillations in the geostrophic state are indeed inertial oscillations and can persist for long times, in agreement with Kuo and Polvani (1997). It was also found that in cases with $Ro \leq \frac{1}{8}$ almost all the energy in the system was trapped within the geostrophic state. In contrast with the non-rotating case, differences in initial wave polarity did not lead to different types of waves, and in both positive and negative polarity cases the dynamics of the wave train were practically identical. We argue that the increase in rotation rate traps more energy in the geostrophic state and as a result the waves ejected are smaller in amplitude. As a result of this reduction in amplitude the dynamics are linear and thus the nonlinear polarity differences disappear. The geostrophic state in these cases exhibits a large isopycnal deflection and thus reflects polarity differences. By extending the spatial extent of our simulation and letting our system evolve for a longer time we have shown that the wave-packet, at the front of the wave-train that is created, does not separate from the tail.

Fully nonlinear stratified geostrophic adjustment problem

A. Coutino and M. Stastna

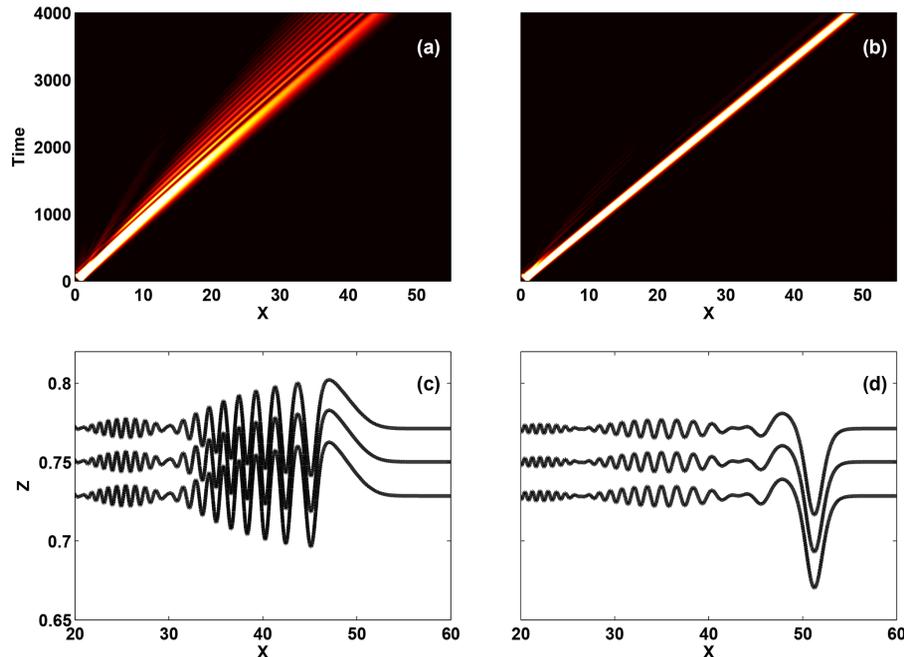

Figure 1. A space–time filled contour plot of vertically integrated kinetic energy and density isocontours at $t = 450$ s (4275) showing the differences between the positive and negative polarity initial conditions with $w = \frac{1}{2}w_0$. **(a)** and **(c)** correspond to the positive polarity case while **(b)** and **(d)** to the negative case.

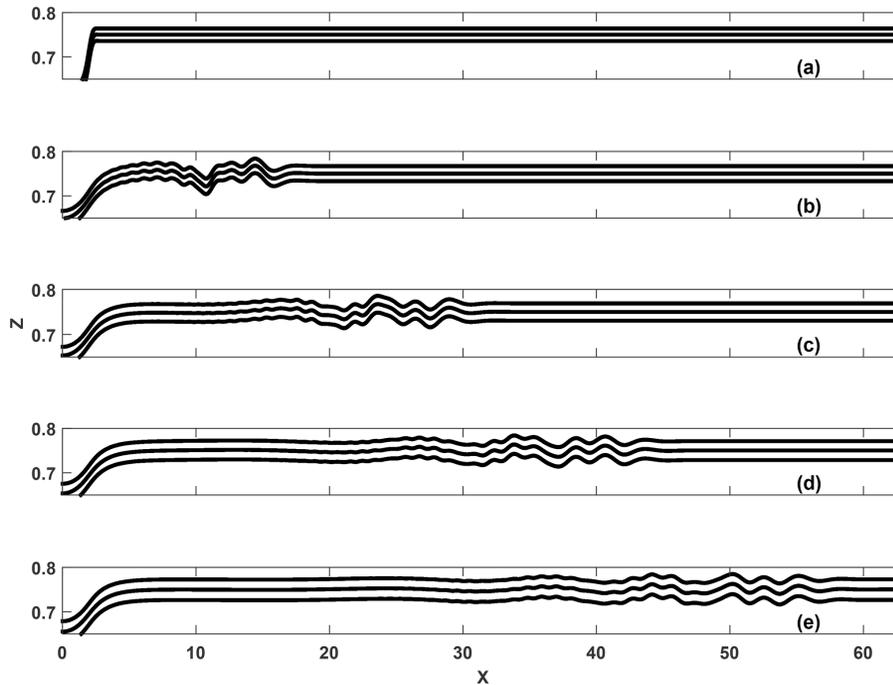

Figure 2. A line plot of density contours which show the time evolution of the waves generated **(a)** corresponds to $t = 0$ s (0), **(b)** to $t = 150$ s (15.75), **(c)** to $t = 300$ s (31.5), **(d)** to $t = 450$ s (47.25) and **(e)** to $t = 600$ s (42).

Fully nonlinear stratified geostrophic adjustment problem

A. Coutino and M. Stastna

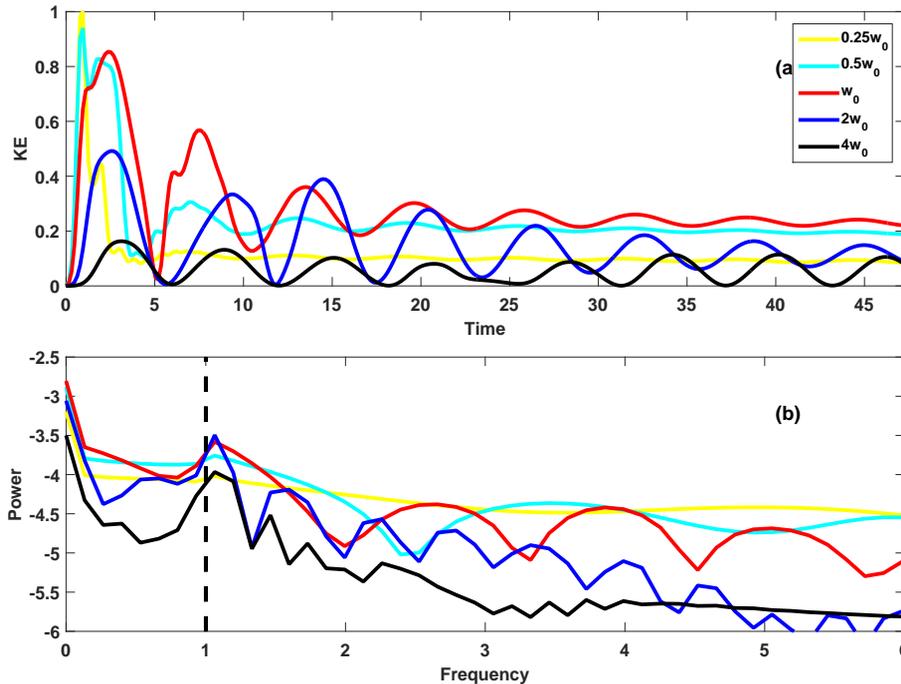

Figure 5. (a) shows a line plot of the vertically integrated kinetic energy found at the midpoint of the geostrophic state for different initial widths through time. (b) corresponds to the logarithm of the spectral power of the time series from (a). The colours represent the different initial rotation rates and the dotted vertical line in (b) is the location of the inertial frequency.

Fully nonlinear stratified geostrophic adjustment problem

A. Coutino and M. Stastna

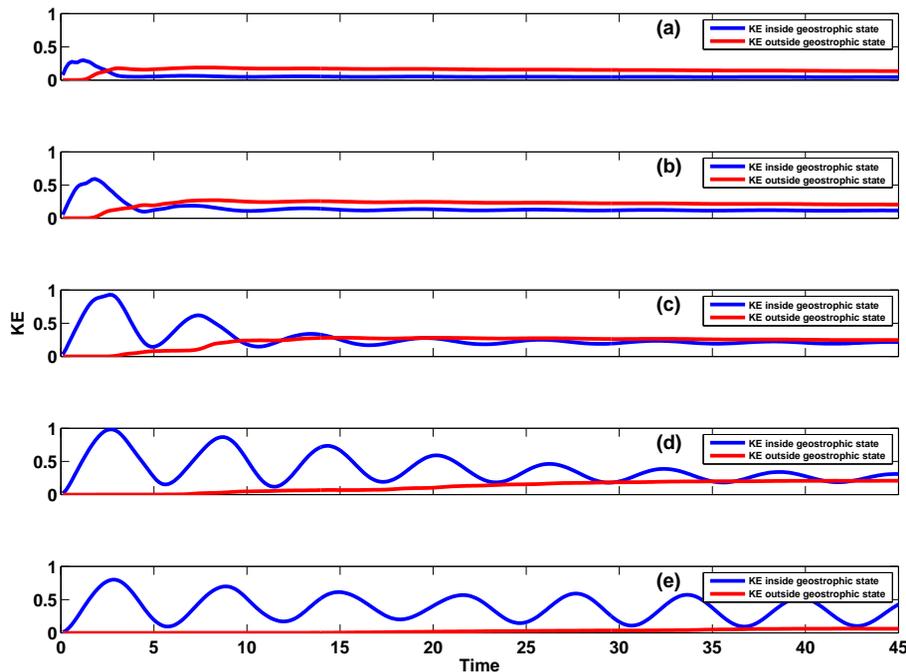

Figure 6. The total kinetic energy located inside (blue) and outside (red) of the geostrophic state. The different panels correspond to the different cases seen in Fig. 4: **(a)** to $w = \frac{1}{4}w_0$, **(b)** to $w = \frac{1}{2}w_0$, **(c)** to $w = w_0$, **(d)** to $w = 2w_0$, and **(e)** to $w = 4w_0$.

Fully nonlinear stratified geostrophic adjustment problem

A. Coutino and M. Stastna

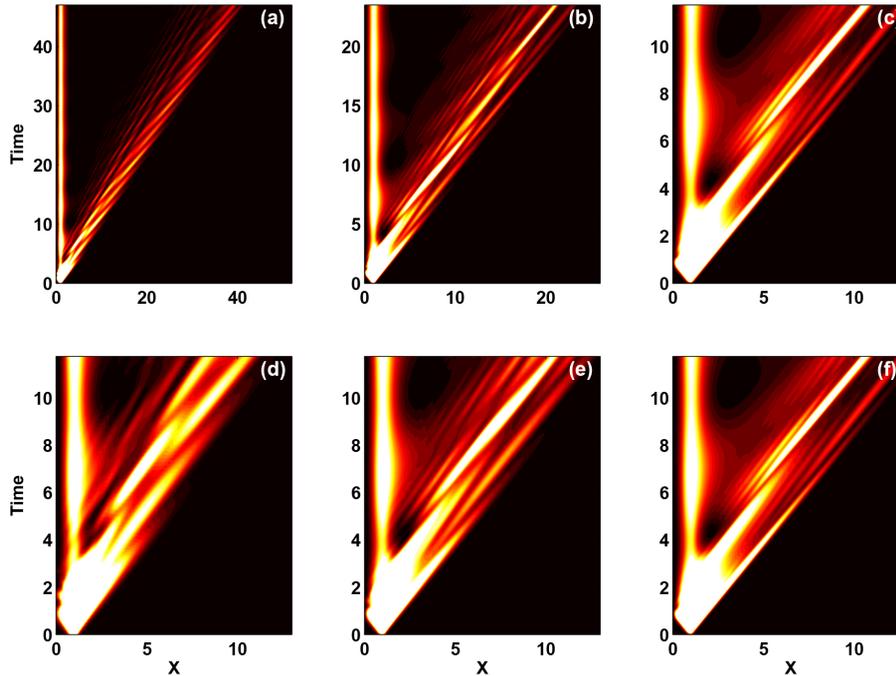

Figure 7. A space–time plot of kinetic energy. The different columns correspond to different f and w used to form a value of $Ro = 1$. **(a)** $f = f_0$ and $w = \frac{1}{2}w_0$, **(b)** $f = \frac{1}{2}f_0$ and $w = w_0$ and **(c)** $f = \frac{1}{4}f_0$ and $w = 2w_0$. The second row corresponds to the same case as the first columns but the aspect ratio has been scaled by the rotation rate.

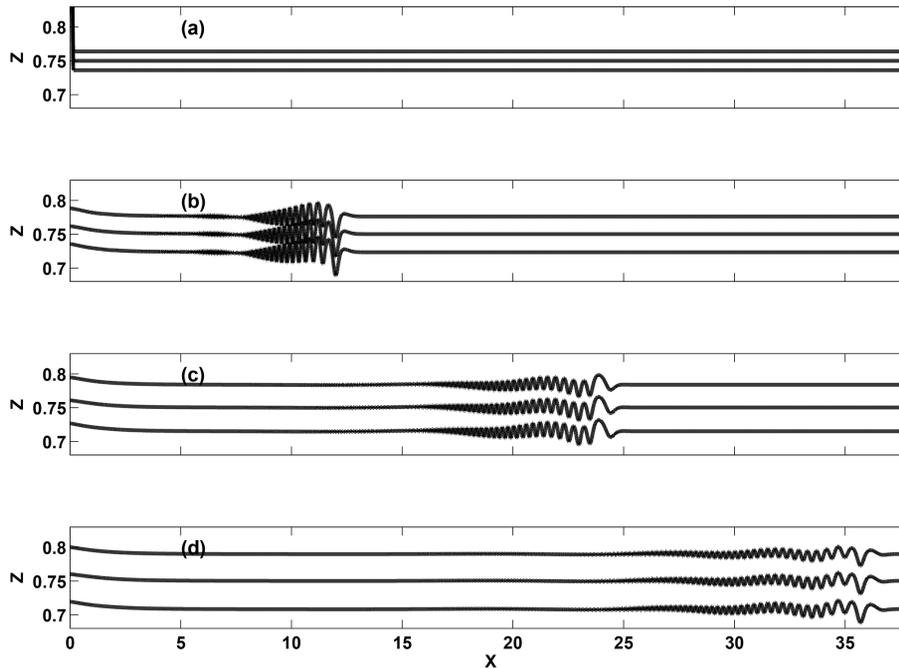

Figure 11. A long-time contour plot of the density field for the case where $f = \frac{1}{8}f_0$ and $w = \frac{1}{2}w_0$. **(a)** corresponds to $t = 0(0)$, **(b)** to $t = 900$ s (11.8), **(c)** to $t = 1800$ s (23.6) and **(d)** to $t = 2700$ s (35.4)

Fully nonlinear stratified geostrophic adjustment problem

A. Coutino and M. Stastna

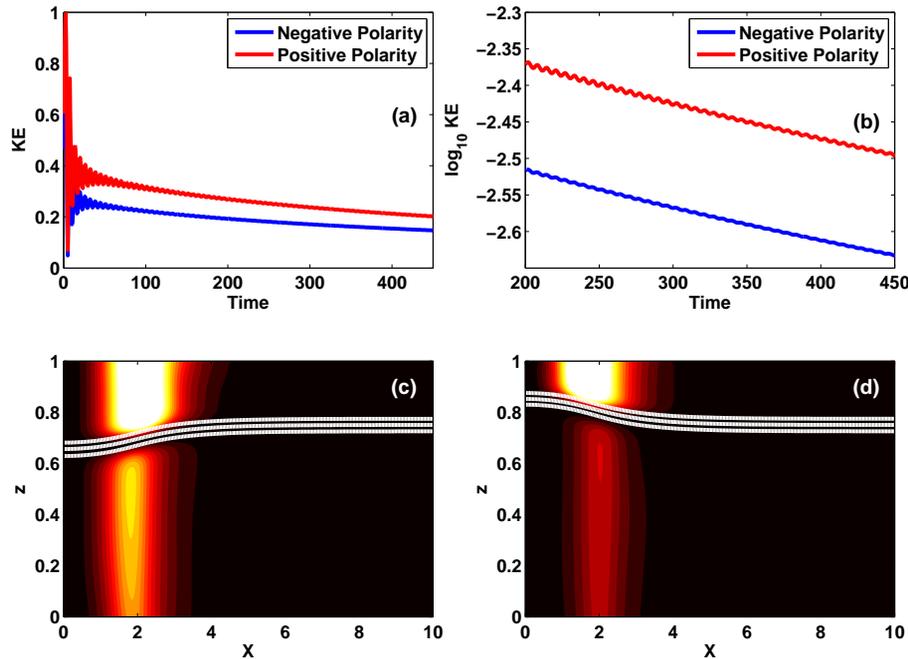

Figure 12. A series of different plots all highlighting features of the geostrophic state for positive and negative polarity cases. **(a)** presents the long-time time-series of vertically integrated kinetic energy in the geostrophic state. **(b)** shows the base ten logarithm of the geostrophic state kinetic energy after the packet has been ejected. **(c)** and **(d)** show the total kinetic energy in the geostrophic state, along with contours of constant density, for a negative and positive initial polarity respectively.

Fully nonlinear stratified geostrophic adjustment problem

A. Coutino and M. Stastna

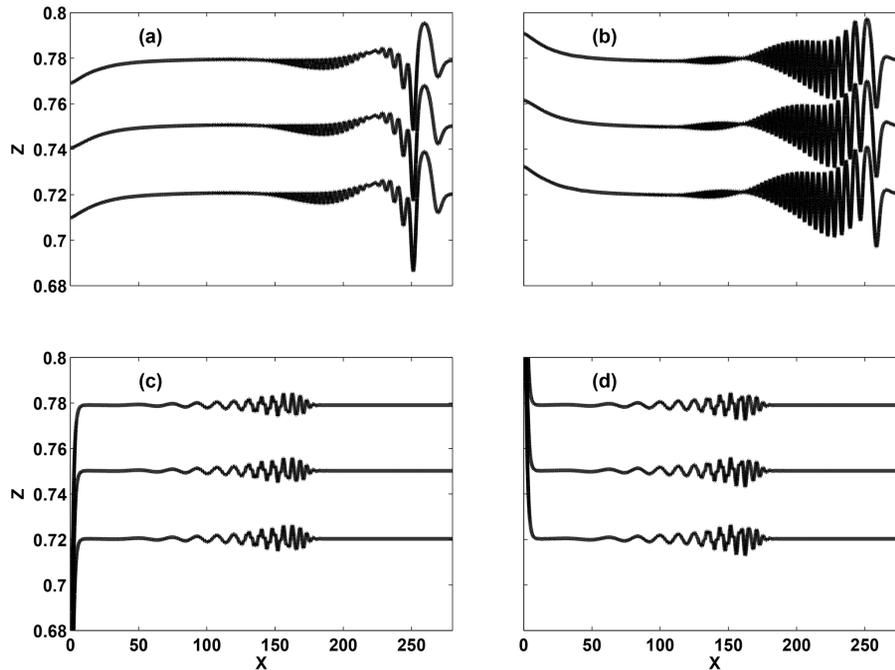

Figure 13. A series of comparisons of the density field across two different rotation rates, $f = 2f_0$ and $f = \frac{1}{8}f_0$ and the two polarities. **(a)** corresponds to $f = \frac{1}{8}f_0$ and negative polarity, **(b)** to $f = \frac{1}{8}f_0$ and positive polarity, **(c)** to $f = 2f_0$ and negative polarity and **(d)** to $f = 2f_0$ and positive polarity.

Fully nonlinear stratified geostrophic adjustment problem

A. Coutino and M. Stastna

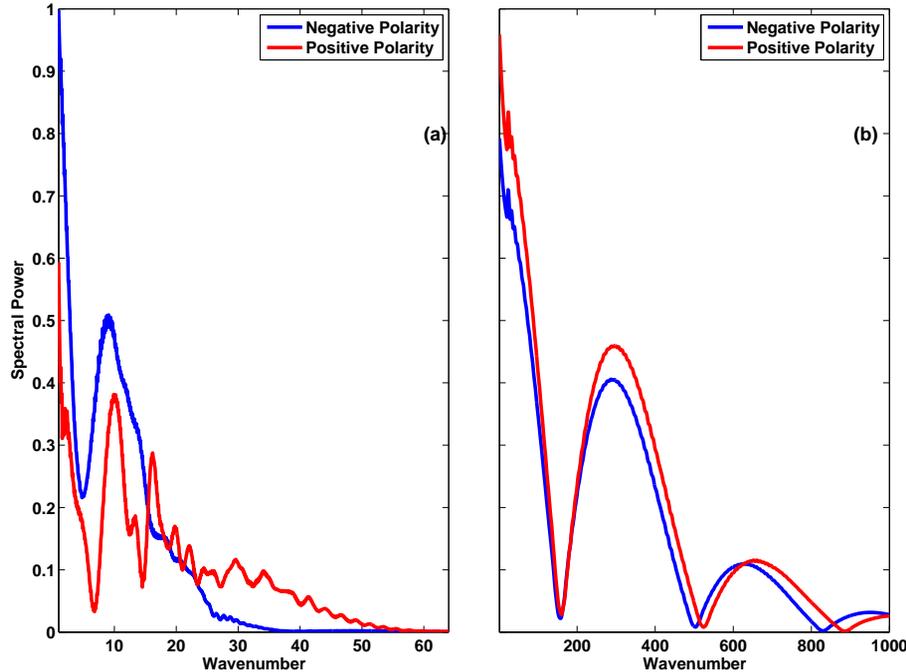

Figure 14. Comparison of the scaled, filtered spectra for different polarities, where **(a)** corresponds to a “low” $f = \frac{1}{8}f_0$ and **(b)** corresponds to a “high” $f = 2f_0$. This figure is taken at 1200 s (15.8 for **(a)** and 252 for **(b)**) and the initial width is $w = \frac{1}{2}w_0$. The spectra has been scaled by the maximum value for each case and the wave-number has been scaled by $\frac{2\pi}{Ro_t}$.

Fully nonlinear stratified geostrophic adjustment problem

A. Coutino and M. Stastna

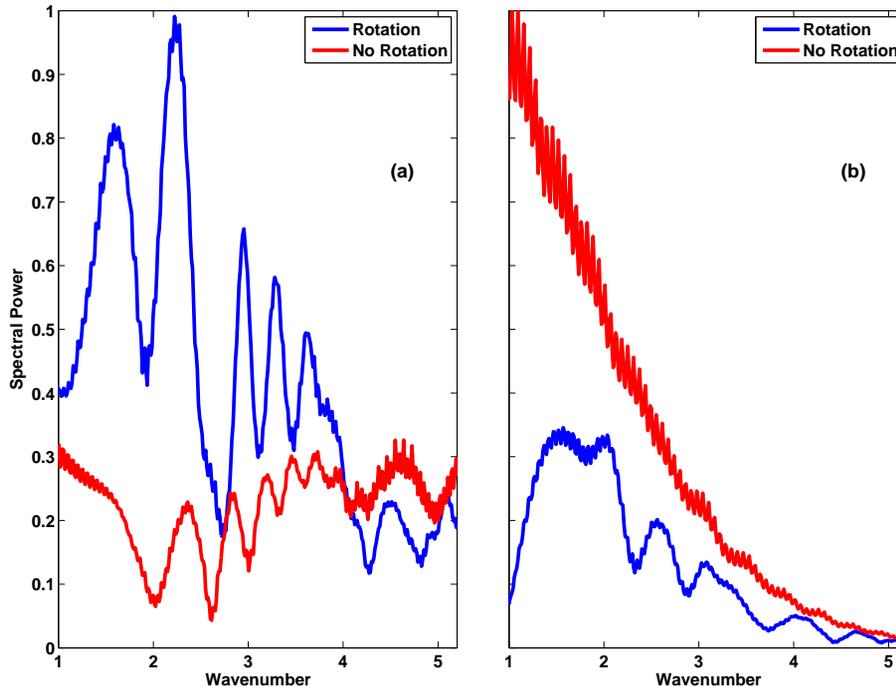

Figure 15. Comparison of the scaled, filtered spectra for no rotation and $f = \frac{1}{8}f_0$, where **(a)** corresponds to an initial wave of elevation and **(b)** corresponds to an initial wave of depression. This figure is taken at 2250 s (29.5 in the rotating case and 236.8 in the non rotating case) and the initial width is $w = \frac{1}{2}w_0$. The spectra have been scaled by the maximum value between the cases and the wave-number has been scaled by $\frac{2\pi}{R_0}$.
