6 Abstract

7 Fluid parcels can exchange water properties when coming in contact with each other, leading to
8 mixing. The trajectory encounter number, which quantifies the number of fluid parcel trajectories
9 that pass close to a reference trajectory over a finite time interval, is introduced as a measure of
10 the mixing potential of a flow. Regions characterized by low encounter numbers, such as cores
11 of coherent eddies, have low mixing potential, whereas turbulent or chaotic regions characterized
12 by large encounter numbers have high mixing potential. The encounter number diagnostic was
13 used to characterize mixing potential in 3 flows of increasing complexity: the Duffing Oscillator,
14 the Bickley Jet, and the altimetry-based velocity in the Gulf Stream Extension region. An
15 additional example was presented where the encounter number was combined with the u-star-
16 approach of Pratt et al., 2016 to characterize the mixing potential for a specific tracer distribution
17 in the Bickley Jet flow. Analytical relationships were derived connecting encounter number to
18 diffusivity for purely-diffusive flows, and to shear and strain rates for linear shear and linear
19 strain flows, respectively. It is shown that in a diffusive regime the encounter number grows as a
20 square-root of time, whereas in a linear shear and strain flows the encounter number is
21 proportional to time.

22 I. Encounter number

23 a. main idea

24 Mixing is an irreversible exchange of properties between different water masses. This process is
25 important for maintaining the oceanic large-scale stratification and general circulation, and it
26 plays a key role in the redistribution of bio-geo-chemical tracers throughout the world oceans.
27 Mixing occurs between different water masses when they come in direct contact with each other.
28 Thus, mixing potential of the flow, i.e., the opportunity for mixing to occur, is generally
29 enhanced in regions where water parcels meet or encounter many other water parcels, such as,
30 for example, within a chaotic zone –a region of the flow that is in a state of chaotic advection.
31 There, the separation between initially nearby water parcels grows exponentially in time and, in
32 the infinite time limit, each water parcel encounters all the other water parcels within the same
33 zone. Similarly, high encounter numbers will exist in turbulent regions. In contrast, mixing
34 potential is expected to be smaller in regions where water parcels do not experience many
35 encounters with other water parcels and remain close to their initial neighbors as the flow
36 evolves. This would be the case, for example, for a water parcel that is located inside a coherent

37 eddy. If the eddy is in a state of solid body rotation, the water parcel would forever stay close to
38 its initial neighbors and will not have any new encounters at all. If some amount of azimuthal
39 shear is present within the eddy, then for a water parcel located at a radius r from the eddy
40 center, encounters will be limited to those water parcels located within a circular strip centered at
41 the same radius r . Of course, the presence of a mixing potential does not guarantee that the
42 mixing of a tracer will occur: it is also essential that the tracer distribution is non-uniform, so that
43 irreversible property exchange can take place between different water parcels during their
44 encounters. Thus, the intensity of mixing would depend on both the tracer distribution and the
45 flow, whereas mixing potential is the property of only the flow field alone.

46 In this work we introduce an objective measure of encounters between different fluid elements in
47 order to quantify the mixing potential of a fluid flow. There are many existing trajectory-based
48 measures of fluid stirring; ours has the virtue of being easy to implement and immediately
49 applicable to ocean float and drifter data. Our method does not require the initial spacing
50 between trajectories to be small (as in Lyapunov exponent – based measures) and does not
51 require sophisticated book keeping as in braid theory (Allshouse and Thiffeault, 2012) or finite-
52 time entropy (Froyland and Padberg-Gehle, 2012).

53 b. definition and numerical implementation

54 For a given reference trajectory, $\vec{x}(\vec{x}_0, t_0; t)$, the encounter number, $N(\vec{x}_0, t_0; t)$, is defined as a
55 number of trajectories starting at the same initial time t_0 that come within a radius R of the
56 reference trajectory over a time interval t . Here t is the trajectory integration time and \vec{x}_0 is the
57 trajectory initial position, i.e., $\vec{x}(\vec{x}_0, t_0; t = 0) = \vec{x}_0$. Regions of space with large/small N would
58 then be associated with enhanced/inhibited mixing potential.

59 We define $N(\vec{x}_0, t_0; t)$ based on the number of encounters with different trajectories, not the total
60 number of encounter events, so even if some trajectory first comes close to the reference
61 trajectory, then moves away and then re-approaches it again later, it is only counted once. In a
62 flow field with no sources or sinks of tracer variance, where variance is therefore decaying, it is
63 reasonable to expect that most property exchange will occur during the first encounter, thus the
64 motive for counting only this first encounter. If tracer variance is being continuously introduced,
65 it may be more reasonable to count the total number of encounters. Even so, the number of first
66 encounters still yields of measure of exposure of a water parcel with other parcels and therefore
67 should still be relevant.

68 For a numerical implementation of the trajectory encounter number-based mixing
69 characterization, one would need to start, at some time t_0 , with a grid of initial positions
70 spanning the flow domain, and then evolve trajectories under the flow field over the time interval
71 t . This time interval should be chosen based on the physical properties of the flow and with
72 specific scientific questions in mind. For example, if the research focus is on ocean submesoscale

73 dynamics, the time scale t would be on the order of hours to days, whereas the corresponding
74 time scale for mesoscale dynamics would be on the order of weeks to months.

75 $N(\vec{x}_0, t_0; t)$ is a Lagrangian quantity that characterizes mixing potential of a flow over a time
76 interval from t_0 to $t_0 + t$. As the flow field evolves in time, its mixing characteristics can change
77 and $N(\vec{x}_0, t_0; t)$ will reflect this change. For example, if a coherent eddy with weak mixing
78 potential, embedded in a chaotic zone with enhanced mixing potential, was present in the flow
79 from time t_1 to time t_2 , but it dispersed and disappeared afterwards, then $N(\vec{x}_0, t_0; t)$ is expected
80 to be small at those locations \vec{x}_0 that correspond to the interior of an eddy for $t_0 \geq t_1$ and
81 $t_0 + t \leq t_2$, whereas for $t_0 > t_2$, when the eddy is no longer present, $N(\vec{x}_0, t_0; t)$ would
82 increase. Dependences on t and t_0 are also expected to be present within a chaotic zone.
83 Although in the infinite time limit, all parcels will encounter all other parcels in a chaotic zone
84 and $N(\vec{x}_0, t_0; t \rightarrow \infty)$ would approach a constant, encounter rates over a finite time interval t are
85 locally the largest near a hyperbolic trajectory and along the segments of its associated stable
86 manifolds, which serve as pathways that bring water parcels into the vicinity of the hyperbolic
87 trajectory. Since locations of hyperbolic trajectories and manifolds generally evolve in time,
88 $N(\vec{x}_0, t_0; t)$ is expected to also vary with t_0 . As the trajectory integration time t increases, water
89 parcels initially located further from the hyperbolic trajectory will have the opportunity to come
90 into its vicinity along the stable manifold. Such parcels, as they approach the hyperbolic
91 trajectory, are expected to have more encounters than their neighbors that are initially located off
92 the manifold and thus bypass the vicinity of the hyperbolic trajectory where many encounters
93 occur. Thus, $N(\vec{x}_0, t_0; t)$ will reveal longer segments of stable manifolds for longer integration
94 times t , as will be illustrated numerically in the next section. This is similar to how the
95 maximizing ridges of the forward time finite-time Lyapunov exponent field, which are often
96 used to approximate stable manifolds of hyperbolic trajectories, elongate and sharpen with
97 increasing integration time (Haller, 2002; Shadden et al., 2005; Lekien and Ross, 2010).

98 The radius R , which defines how close to a reference trajectory should another trajectory come in
99 order to be counted as an encounter, is an important parameter for the calculation of the
100 encounter number N . Generally, R should be small compared to the spatial scale of the smallest
101 features of interest. Specifically, for the N field to delineate a flow feature, say, an eddy,
102 trajectories within the eddy interior should not encounter those on its exterior. The boundary
103 region near the eddy perimeter, where such encounters can occur, has the width $2R$. So, if that
104 width is comparable to or larger than the eddy size, then the eddy would get completely smeared
105 out and will not be resolved. From a practical viewpoint, however, using very small R would
106 require very dense grids of trajectories to be computed, otherwise zero or very small number of
107 trajectory encounters will occur in the entire flow domain. Numerical examples in the next
108 section suggest that choosing R to be a fraction, up to about half of the size of the smallest
109 features of interest work best.

110 Once the time scale t is identified, trajectories are computed, and radius R is chosen, the number
 111 of encounters, $N(\vec{x}_0, t_0; t)$, needs to be counted for each trajectory and plotted as a function of
 112 the trajectory initial position \vec{x}_0 . The resulting N field will delineate the flow regions with
 113 different mixing properties as subdomains having different values of N .

114 II. Examples

115 We proceed to test the performance of the encounter number technique in quantifying mixing
 116 potential for several geophysically relevant sample flows of increasing complexity, starting from
 117 a simple analytically prescribed periodically perturbed double-gyre Duffing Oscillator system,
 118 followed by a dynamically consistent solution of the PV conservation equation on a beta-plane
 119 known as the Bickley Jet, and finishing with an observationally based geostrophic velocity field
 120 in the North Atlantic derived from the sea surface height altimetry.

121 a. Duffing Oscillator

122 The Duffing Oscillator flow and its figure-eight geometry has become a standard test case for
 123 emerging techniques related to the dynamical systems theory. This flow consists of two gyres
 124 with the same sign of rotation (clockwise in our case), whose elliptic centers oscillate in time
 125 around their mean position. A hyperbolic point is located at the origin between the two gyres,
 126 and a pair of stable and unstable manifolds emanate from it forming a figure eight in the absence
 127 of the time dependent perturbation, or forming a classic homoclinic tangle in the presence of the
 128 perturbation. The velocity field is two-dimensional and incompressible and is given by $u = y$
 129 and $v = (x - ax^3)(1 + \epsilon \cos(\omega t + \phi))$ with $a = 1$, $\omega = 3\pi/2$, $\phi = \pi/4$ and $\epsilon = 0.1$. With
 130 these parameters, the Poincare section (Fig. 1 bottom) shows the presence of two main regular
 131 elliptic regions with $O(1)$ radius corresponding to the interiors of the gyres, which are embedded
 132 into a figure-eight shaped chaotic zone, within which a number of island chains with smaller
 133 regular islands are present. The winding time for most trajectories in the system is on the order of
 134 $5T_{pert}$ with $T_{pert} = \frac{2\pi}{\omega}$, except for trajectories near the hyperbolic point for which winding time
 135 is much longer (Fig. 1 top).

136 The encounter number was computed for a range of trajectory integration times, from $T = T_{pert}$
 137 (which is significantly shorter than trajectory winding time) to $T = 50T_{pert}$ (significantly longer
 138 than trajectory winding time), and for a range of encounter radii, from $R = 0.01 \ll R_{eddy}$
 139 (significantly smaller than the eddy core radius) to $R = 1 \approx R_{eddy}$ (comparable to the eddy core
 140 radius). The results in Fig. 2 suggest that the encounter number method works best for
 141 integration times longer than the trajectory winding time and encounter radius about 1/3 to 1/2 of
 142 the gyre radius (right 3 panels of the middle row). For very small encounter radius (top row), N
 143 is noisy because trajectories simply do not encounter many neighbors. Thus, delineating the
 144 domain into regions with different mixing potential, as in the top right panel, requires long
 145 integration time. For $T = 50T_{pert}$, good agreement with Poincare section is observed, and the

146 use of small encounter radius allows for a precise identification of smaller regular island chains,
147 such as the chains of 4 islands located just outside of the perimeter of both left and right eddy
148 cores. Note that the noise in the N field can be suppressed by using a denser initial grid of
149 trajectories, but at the cost of a more expensive computation. For very short integration times
150 (left column) when trajectory segments are very short, the encounter number is not capturing the
151 difference between the regular and chaotic regions. This is not surprising as velocity shear is
152 probably a dominating factor over such small times. As the integration time increases, the
153 difference in encounter number becomes more pronounced between trajectories that remain
154 within the eddy cores and trajectories that are free to move around the chaotic zone. Over a time
155 scale of approximately one winding period (or about 5 periods of the perturbation; second
156 column), the two regular eddy cores (blue regions with small N) and a segment of the stable
157 manifold (red curve emanating from the origin with largest N) becomes clearly visible for $R=0.2$
158 and $R=1$. The revealed manifold segment becomes longer, narrower and more tangled,
159 eventually filling up the whole chaotic zone. At the same time, the shape of the core region
160 becomes more exact and approaches the “true” core in the Poincare section as the integration
161 time increases to 50 periods of the perturbation. The agreement with Poincare section is excellent
162 in the right middle panel, although the smaller island chains are not as visible as in the top right
163 panel because of the use of a larger encounter radius that is comparable to their size (see Fig. 3).
164 Finally, for the large encounter radius that is comparable to the size of the eddy (bottom row),
165 the boundary region near perimeter of an eddy, within which trajectories on the inside of the
166 eddy can encounter trajectories passing by on the outside, is as wide as the eddy itself, essentially
167 wiping out all small scales from the N field. All of these trends are in agreement with theoretical
168 expectations described in Section I.

169 b. Bickley Jet

170 The meandering Bickley jet flow is an idealized, but linearly dynamically consistent, model for
171 the eastward zonal jet in the Earth’s Stratosphere (Rypina et al., 2007a; Rypina et al., 2011).
172 This flow consists of a steady eastward zonal jet on which two eastward propagating Rossby-like
173 waves are superimposed. All flow parameters used here are identical to those used in our
174 previous 2007 and 2011 papers. In the reference frame moving at a speed of one of the waves,
175 the flow consists of a steady background velocity subject to a time periodic perturbation. The
176 background looks like a meandering jet, with three recirculation gyres to the north and south of
177 the jet core. Between the recirculation gyres, there are three hyperbolic points with the associated
178 stable and unstable manifolds. Under the influence of the time-periodic perturbation imposed by
179 the second wave, heteroclinic tangles are formed by the manifolds emanating from different
180 hyperbolic regions between the recirculations, and a chaotic zone emerges on either side of the
181 jet. The manifolds, however, cannot penetrate through the jet core, which remains regular and
182 acts as a transport barrier separating the northern and southern chaotic zones. All of these
183 features are clearly visible in the Poincare section shown in Fig. 4 (top). The bottom subplot
184 shows the N field computed using the encounter radius $R=5*10^5$, which is about half of the

185 recirculation region radius, and using trajectory integration time on the order of a few winding
186 times within the recirculations. As expected, the encounter number identified 6 recirculation
187 regions and the jet core as zones with small mixing potential (blue). 6 blue recirculation regions
188 are embedded into two distinct chaotic zones with enhanced mixing potential (yellow-red) on
189 either side of the jet. Mixing potential is the largest (red) along the segments of stable manifolds
190 emanating from the hyperbolic trajectories between recirculations.

191 c. Altimetry-based velocity in the meandering Gulf Stream region

192 The flow in the Gulf Stream Extension region, with a non-steady meandering jet that sheds
193 coherent eddies and recirculations to the north and south, has a lot in common, at least
194 qualitatively, with the Bickley Jet example. Unlike the idealized model, however, the real
195 oceanic eddies have finite lifetimes, and the jet is not periodic in the zonal direction.
196 Nevertheless, many of the qualitative features of the Bickley Jet's N field hold in this example.
197 Specifically, trajectories inside coherent eddy cores have smaller encounter number than their
198 surroundings, and the jet centerline has smaller encounter number than the flanks.

199 The velocity field that we used was downloaded from the AVISO website
200 (<http://www.aviso.altimetry.fr/en/data/products/sea-surface-height-products/global.html>) and
201 corresponds to their gridded product with $\frac{1}{4}$ deg spatial resolution and temporal step of 1 day.
202 This velocity is based on the altimetric sea surface height measurements made from satellites.
203 The heights were converted into velocities using geostrophic approximation. For the encounter
204 number estimation, trajectories were seeded on a regular grid with $dx = dy \cong 0.06$ deg on 11
205 July 1997 and were integrated forward in time for 90 days using a fifth-order variable-step
206 Runge-Kutta integration scheme with bi-linear interpolation between grid points in space and
207 time. The encounter radius was chosen to be 0.3 deg, which is about a third of the radius of a
208 typical 200-meter-wide Gulf Stream ring.

209 The encounter number was estimated for three different integration times, $T = 30$ days, 60 days
210 and 90 days (Fig. 5). The N field reveals that a number of coherent eddies were present on both
211 sides of the meandering jet on 11 July 1997. Among those, two strongest ones can be seen at
212 54W, 36N and 52W, 41N, with the low-N (blue) core and high-N (red) perimeter. As the
213 integration time increases from 30 days to 90 days, the eddies start to leak fluid, their cores start
214 to lose coherence, and the encounter number within the eddy core starts to increase as more and
215 more trajectories escape into the eddy surroundings over time. To visualize this behavior, we
216 extracted trajectories from the core of the northern eddy in Fig. 5(left) (i.e., trajectories with
217 $N < 100$ from the 30-day-long N field), and plotted their subsequent positions after 30 days, 60
218 days and 90 days. The results in Fig. 6 confirm that the eddy core stays completely coherent over
219 30 days (i.e., all trajectories stay together), but starts to deteriorate at 60 days, with only a small
220 fraction of the initial patch still staying together and the rest of the patch dispersing and forming
221 long and narrow filaments.

222 The jet region, although noisy, seems to suggest higher N near the flanks and smaller near the
 223 centerline. The center region is not as well-defined as in the Bickley Jet example, possibly
 224 because the Gulf Stream inhibits but does not fully prevent the meridional transport in this
 225 region, and because our encounter radius might have been too large to reveal the central region,
 226 if the true center region was narrower than $2R$ (0.6 degrees). Finally, the N field suggests that the
 227 mixing potential of the flow is not symmetric with respect to the jet centerline and is higher on
 228 the northern side. It would be interesting to see if this is a general property of the flow in this
 229 region or if this phenomenon is specific to the time interval chosen. This investigation is left for
 230 future study.

231 III. Connection between the encounter number and diffusivity, shear and strain rate for a
 232 diffusive, linear shear and linear strain flows, respectively

233 By analogy with molecular diffusion, eddy diffusivity is often used to characterize the eddy-
 234 induced downgradient tracer transfer in realistic geophysical fluid flows. Because of the
 235 simplicity of this approach, the majority of existing non-eddy-resolving oceanic numerical
 236 models are diffusion based, despite the somewhat questionable assumptions underlying this
 237 approach.

238 A connection between the encounter number and diffusivity (LaCasce 2008; Vallis, 2006;
 239 Rypina et al., 2015; Kamenkovich et al., 2016) can be derived under the assumption of a
 240 diffusive random walk particle motion, where the root-mean-square (RMS) distance from
 241 particle's initial position grows in time, on average, in proportion to $r_{RMS}(t) \sim \sqrt{Kt}$ with K
 242 denoting the diffusivity. To derive the expression for the encounter number for such process, it is
 243 convenient to move to a reference frame that is tied to a reference particle, which would then
 244 always stay at the origin, while other particles would be involved in a random walk motion. Over
 245 a time interval t, those particles that are located within a circular strip between radii R and
 246 $R+r_{RMS}(t)$ will have a chance to encounter the reference particle, i.e., to enter into a circle of
 247 radius R around the origin. For particles released on a regular grid with spacing dx and dy
 248 between the neighbors in the x and y directions, respectively, the number of particles within such
 249 circular strip is $n = \frac{S}{dxdy}$ where S is the area of the strip. Not all of the particles within this
 250 circular strip, however, will necessarily move toward the origin; some will move away and thus
 251 will not encounter the reference particle. Since the random walk process does not have a
 252 preferred direction, for a particle located at a distance r from the origin, the probability to move
 253 towards the reference particle and enter into a circle of radius R, as opposed to bypassing this
 254 circle, is $P(r) = \frac{\alpha}{\pi} = \frac{\text{Arcssin}(\frac{R}{r})}{\pi}$ where α is the angle between the direction to the origin and the
 255 tangential direction to the circle of radius R, as indicated in Fig. 7. The encounter number for our
 256 reference particle can then be written as

$$\begin{aligned}
 N &= \frac{1}{dxdy} \int_0^{2\pi} d\theta \int_R^{R+r_{\text{RMS}}} rP(r)dr = \frac{2}{dxdy} \int_R^{R+r_{\text{RMS}}} r \text{Arc sin} \frac{R}{r} dr = \\
 257 \quad &= \frac{1}{dxdy} \left[rR \left(1 - \frac{R^2}{r^2} \right)^{1/2} + r^2 \text{Arc Sin} \frac{R}{r} \right]_R^{R+r_{\text{RMS}}} \xrightarrow{r_{\text{RMS}} \rightarrow \infty} \frac{2}{dxdy} rR \Big|_R^{R+r_{\text{RMS}}} \sim \frac{2R\sqrt{Kt}}{dxdy}, \tag{1}
 \end{aligned}$$

258 where the last two expressions correspond to a long time limit.

260 The ballistic spreading that is dominated by a local velocity shear is another commonly-
 261 encountered spreading regime. There, the separation between particles grows in proportion to
 262 time. Ballistic spreading can often be observed in nonsteady realistic oceanic flows at time scales
 263 that are much shorter than the onset of diffusive spreading (which develops after a trajectory
 264 samples multiple different eddies or other flow features). To derive a connection between
 265 encounter number and velocity shear, consider a trajectory that is advected by a flow field with
 266 linear meridional velocity shear, γ , of zonal velocity. In a reference moving with a reference
 267 trajectory the velocity profile is, $u(y) = \gamma y$ where u denotes the x-component of velocity, and
 268 the encounter number becomes

$$269 \quad N = \frac{2}{dxdy} \int_0^R dy \int_R^{R+x(t)} dx = \frac{2}{dxdy} \int_0^R dy \int_0^t u(y) dt = \frac{\gamma R^2 t}{dxdy}, \tag{2}$$

270 suggesting a faster linear growth with time for a ballistic regime, compared to a slower square-
 271 root dependence for purely diffusive motion.

272 The steady linear saddle flow with a constant strain rate α and velocities

$$273 \quad u = \alpha x; v = -\alpha y. \tag{3}$$

274 is another commonly-considered example often used to approximate the vicinity of a hyperbolic
 275 trajectory in more complicated non-steady non-linear situations. A unique property of this flow is
 276 that the velocity profile is unchanged in any reference frame moving with a trajectory. This can
 277 be shown by applying the coordinate transformation, $\hat{x} = x - x_{tr}(t)$; $\hat{y} = y - y_{tr}(t)$, where
 278 $(x; y)$ are coordinates in a stationary frame, $(\hat{x}; \hat{y})$ are coordinates in a moving frame, and
 279 $(x_{tr}(t); y_{tr}(t))$ is the trajectory. The velocity in a moving frame is then

$$\begin{aligned}
 280 \quad \hat{u} &= u - \frac{dx_{tr}}{dt} = \alpha x - \frac{dx_{tr}}{dt} = \alpha \hat{x} + \alpha x_{tr} - \frac{dx_{tr}}{dt} = \alpha \hat{x} \\
 \hat{v} &= v - \frac{dy_{tr}}{dt} = -\alpha y - \frac{dy_{tr}}{dt} = -\alpha \hat{y} - \alpha y_{tr} - \frac{dy_{tr}}{dt} = -\alpha \hat{y}
 \end{aligned} \tag{4}$$

281 where the last equality holds because $\frac{dx_{tr}}{dt} = \alpha x_{tr}$; $\frac{dy_{tr}}{dt} = -\alpha y_{tr}$. Thus, without loss of
 282 generality, we can consider a flow in a reference frame moving with a reference trajectory that is

283 located at the origin. The number of trajectories that come within a radius R of the origin over
 284 the time interval T can be written as

$$285 \quad N = \frac{1}{dxdy} \int_0^T F_{\perp}(t) dt, \quad (5)$$

286 where dx and dy denote the grid spacing between neighboring trajectories, and the flux of
 287 trajectories entering the circle is given by

$$288 \quad F_{\perp} = \int u_{\perp} ds. \quad (6)$$

289 Here u_{\perp} is the inward-looking normal component of velocity at a circle of radius R , and ds is an
 290 infinitesimal segment of the circle arc. From symmetry, the flux is the same in each of the 4
 291 quadrants so we will consider the 1st quadrant only. From geometry (Fig. 7 (right)),

292 $u_{\perp} = -u \sin \beta - v \cos \beta = \alpha R (\cos^2 \beta - \sin^2 \beta)$ and $ds = R d\beta$, leading to

$$293 \quad F_{\perp}^{1st \text{ quad}} = \alpha R^2 \int_0^{\pi/4} (\cos^2 \beta - \sin^2 \beta) d\beta = \frac{\alpha R^2}{2} \quad (7)$$

294 and

$$295 \quad N^{1st \text{ quad}} = \frac{1}{dxdy} \int_0^T F_{\perp}(t) dt = \alpha R^2 T / 2. \quad (8)$$

296 Adding the other 3 quadrants then gives

$$297 \quad N = \frac{2\alpha R^2 T}{dxdy}. \quad (9)$$

298 The linear growth of the encounter number with time in the linear shear and linear strain flows
 299 could be anticipated by noting that both flows are steady in a reference frame moving with a
 300 reference trajectory, and all particles only encounter the origin once and never come back. Thus,
 301 the flux through the encounter circle is constant in time and the encounter number, which is a
 302 time-integral of flux, is proportional to time. The random walk flow is different because the
 303 particles can encounter the reference trajectory more than once, leading to a non-steady flux of
 304 first encounters and a non-linear time dependence of the encounter number.

305 IV. Mixing potential for a specified tracer: the \mathbf{u}^* -approach

306 The above examples are centered on mixing potential of a flow field, but there may be value in
 307 computing the encounter number for swarms of trajectories of biological organisms, drifting
 308 sensors, and other non-Lagrangian trajectories. For example, if one is interested in the actual
 309 transport of scalar properties such as heat, salt, or vorticity, then it may be useful to calculate N
 310 using a velocity field that is directly linked to the vector flux of the scalar of interest. This

311 linkage is made explicit by Pratt et al. (2016), who define velocity field \mathbf{u}^* based on the (known)
312 flux \mathbf{F} of a scalar with concentration C . Here bold quantities denote vectors. The concentration is
313 assumed to obey a conservation equation of the form

$$314 \quad \frac{\partial C}{\partial t} = -\nabla \cdot \mathbf{F} + S, \quad (10)$$

315 where S contains the sources and sinks of C . The velocity \mathbf{u}^* is defined as the velocity of a
316 hypothetical flow in which the flux of C is purely advective: $\mathbf{F} = C\mathbf{u}^*$. It can be shown that, in
317 the absence of sources or sinks of C , that the total amount of C contained within any material
318 boundary advected by this hypothetical flow is conserved: $\frac{d}{dt} \int_V C dV = 0$. Thus \mathbf{u}^* is linked to
319 scalar property fluxes while \mathbf{u} is limited to fluid volume (or area) fluxes.

320 If indeed \mathbf{F} is due entirely to advection by the actual fluid velocity field \mathbf{u} , then $\mathbf{u}^* = \mathbf{u}$, but more
321 generally \mathbf{F} will contain contributions from eddy fluxes, molecular or sub-grid diffusion, and
322 even forcing and dissipation terms that can be expressed as the divergence of a flux. In addition,
323 \mathbf{F} may be augmented by the addition of any non-divergent vector without altering Eq. (3).
324 Although this lack of uniqueness may seem troublesome, it provides a degree of flexibility that
325 can be exploited, as we demonstrate below. Thus, by estimating the encounter number N for
326 trajectories of the \mathbf{u}^* field, one is quantifying the rate at which different tracer parcels are
327 brought into contact with each other. An example is presented next.

328 a. Example: encounter number for a tracer with a specified initial distribution in a
329 Bickley Jet flow

330 In this subsection we apply the encounter number diagnostic to quantify the mixing potential for
331 a specific tracer in the Bickley Jet flow. Our goal is to describe an example where the \mathbf{u}^* field for
332 a given tracer is significantly different from the flow velocity \mathbf{u} , and where the corresponding
333 encounter number field for a given tracer, N^* , is significantly different from the water particle
334 trajectory-based encounter number N .

335 Consider the Bickley Jet flow with the same parameters as in II(b) and assume that one is
336 interested in a tracer that is, at initial time t_0 , completely flat south of the jet and has a constant
337 meridional gradient north of the jet, i.e., $C_0 = c_0 + 0.5y(\text{sign}(y - 5 * 10^5) + 1)$ with $c_0 = 1$.
338 Ignoring the diffusive terms, the tracer evolution is governed by the advection equation $\frac{\partial C}{\partial t} =$
339 $-\nabla(\mathbf{u} \cdot C)$, where \mathbf{u} is the Bickley Jet flow velocity. Since the jet core acts as a transport barrier
340 separating the northern and southern chaotic zones, this tracer will rapidly filament and develop
341 high property gradients north of the jet, but will remain flat south of the jet. So, despite the fact
342 that the mixing potential of the Bickley Jet flow is exactly the same on both sides of the jet (Fig.
343 3(bottom)), stirring will not lead to mixing for this particular tracer distribution south of the jet,
344 where tracer gradient is zero, thus leading to zero mixing potential for this particular tracer. We

345 seek to capture this effect via applying the encounter number-based mixing diagnostic to the
346 corresponding \mathbf{u}^* field for this tracer.

347 In this example, it is most convenient to make use of the flexibility in the definition of the tracer
348 flux and define \mathbf{F} to be the flux of a tracer anomaly with respect to the value south of the jet,
349 $\mathbf{F} = \mathbf{u} \cdot (C - c_0)$. This is allowed because the additional flux vector, $\mathbf{F}_1 = -\mathbf{u}c_0$, is non-
350 divergent. The resulting $\mathbf{u}^* = \frac{\mathbf{F}}{c} = \mathbf{u} \left(1 - \frac{c_0}{c}\right)$ is zero south of the jet where $C = c_0$ and is
351 approximately equal to \mathbf{u} north of the jet where $C \gg c_0$, leading to the \mathbf{u}^* -based encounter
352 number $N^* = 0$ south of the jet and $N^* \approx N$ north of the jet.

353 This behavior was further validated numerically in Fig. 8, where we first numerically simulated
354 the evolution of this tracer in the Bickley Jet flow, then estimated \mathbf{u}^* and counted N^* for
355 trajectories advected by the \mathbf{u}^* field. The result confirms that mixing potential for this tracer is
356 zero south of the jet, $N^* = 0$, whereas north of the jet N^* is very close to N from Fig. 4(bottom).
357 Thus, by combining the \mathbf{u}^* approach of Pratt et al., 2016 with the encounter number idea, we
358 were able to correctly capture the mixing potential for a specific tracer.

359 V. Summary and discussion

360 When water parcels come in direct contact with each other, they can exchange water properties,
361 leading to mixing. The trajectory encounter number, N , quantifies the number of fluid parcel
362 trajectories that pass close to a reference trajectory over a time interval T . Thus, the encounter
363 number is proportional to, and can be used as a measure of, the mixing potential of a flow.

364 The encounter number diagnostic was tested in 3 flows with increasing complexity, the Duffing
365 Oscillator, the Bickley Jet, and the altimetry-based velocity in the Gulf Stream Extension region.
366 In all cases, N was smaller within cores of coherent eddies and jets, where mixing potential was
367 low, and N was larger in chaotic zones near the perimeters of the eddies and at the flanks of the
368 meandering jets, where the mixing potential of the flow was high.

369 Similar to finite-time Lyapunov exponents (FTLEs) that are commonly used to delineate regions
370 with qualitatively different motion (Haller, 2002; Shadden et al., 2005; Lekien and Ross, 2010),
371 N depends on the trajectory starting time, t_0 , allowing tracking the evolution of oceanic features
372 by repeating the calculation at different t_0 , and on the trajectory integration time, T , revealing
373 different structures that impact the mixing potential of the flow from time t_0 to time t_0+T .
374 Specifically, longer segments of manifolds emanating from hyperbolic regions are revealed for
375 longer T . In the long- T limit, when manifolds fill in the entire chaotic zone, N approaches a
376 constant equaling to the number of trajectories initially released within the chaotic zone. N also
377 depends on the encounter radius R , which defines how close two trajectories need to be in order
378 to be counted as an encounter. Analytic arguments and numerical simulations both suggest that R
379 on the order of a fraction ($\sim 1/3$) of the radius of the smallest feature of interest should work well
380 in most cases. Finally, the encounter number N depends on the initial spacing between

381 neighboring trajectories. For identifying regions with enhanced or inhibited mixing potential
382 within the same flow, such as coherent eddy cores, jet cores, manifolds and chaotic zones, this
383 dependence is not important, provided that the initial grid was regular and spacing was the same
384 throughout the entire domain. If needed, this dependence can be easily eliminated by
385 normalizing the encounter number by the number of initial neighbors within the encounter
386 radius. We did not implement this normalization in our examples.

387 As with FTLEs, complexity measures (Rypina et al., 2011), Lagrangian descriptors (Mendoza et
388 al., 2014) and other techniques from the dynamical systems theory (Beron-Vera et al., 2013;
389 Budisic and Mezic, 2012; Froyland et al., 2007; Haller et al., 2016), N can be computed for
390 forward and backward in time trajectories, with the backward computation revealing unstable
391 manifolds.

392 The analytic connection between trajectory encounter number and a widely-used measure of
393 mixing, the diffusivity K , was derived under the assumption of a purely-diffusive random walk
394 process, where it was shown that $N \propto \sqrt{Kt}$. On the other hand, for a ballistic spreading regime
395 dominated by the velocity shear γ , and for the linear saddle flow with a constant strain α , N was
396 shown to be proportional to γt and αt , respectively. The linear growth of the encounter number
397 with time for the linear shear and linear strain flows is a consequence of the steady flux of first
398 encounters through the encounter circle. The non-linear dependence for the diffusive flow is
399 caused by the repeated encounters of particles with a reference trajectory leading to the flux of
400 first encounters that decreases with time.

401 The mixing potential is the property of the flow field and characterizes the intensity of stirring,
402 whereas the actual tracer mixing depends both on the flow and the tracer. For example, no tracer
403 mixing will occur if the tracer gradient is zero, even if the mixing potential of the flow is high.
404 To address this, we have proposed combining the encounter number diagnostic with the \mathbf{u}^* -
405 approach of Pratt et al, 2016 for characterizing the mixing potential for a specific tracer C . \mathbf{u}^*
406 depends on, and includes information about, the tracer fluxes. In the absence of sources and sinks
407 of C , the amount of tracer is conserved within any Lagrangian volume advected by \mathbf{u}^* , so the
408 encounter number N^* computed for trajectories advected by \mathbf{u}^* can be used to quantify the
409 mixing potential for a specific tracer. An example was presented where N^* for a specified tracer
410 distribution in the Bickley Jet flow was significantly different from N in a large part of the
411 domain.

412 The encounter number is a frame-independent quantity because it is based on relative distances
413 between water parcel trajectories, rather than on properties of isolated trajectories. The encounter
414 number values do not change under orthogonal transformations of coordinates, i.e., under
415 rotations and translations of a reference frame. This is a desirable property because the ability of
416 a flow to mix tracers should not depend on the reference frame.

417 The encounter number ideas presented in this paper are not restricted to two-dimensional flows
418 and do not require incompressibility, although all flow fields (except u^*) considered here were
419 two-dimensional and incompressible. The encounter number can be used to quantify mixing
420 potential in three-dimensional flows, but this extension is left for a future study.
