9

10 *Abstract:* The aftershock productivity law is an exponential function of the form
11 $K \propto \exp(\alpha M)$ with K the number of aftershocks triggered by a given mainshock of
12 magnitude M and $\alpha \approx \ln(10)$ the productivity parameter. This law remains empirical
13 in nature although it has also been retrieved in static stress simulations. Here, we
14 explain this law based on the Solid Seismicity Postulate (SSP), the basis of a
15 geometrical theory of seismicity where seismicity patterns are described by
16 mathematical expressions obtained from geometric operations on a permanent static
17 stress field. We first test the SSP that relates seismicity density to a static stress step
18 function. We show that it yields a power exponent $q = 1.96 \pm 0.01$ for the power-law
19 spatial linear density distribution of aftershocks, once uniform noise is added to the
20 static stress field, in agreement with observations. We then recover the exponential
21 function of the productivity law with a break in scaling obtained between small and
22 large M , with $\alpha = 1.5\ln(10)$ and $\ln(10)$, respectively, in agreement with results from
23 previous static stress simulations. Possible biases of aftershock selection, verified to
24 exist in Epidemic-Type Aftershock Sequence (ETAS) simulations, may explain the
25 lack of break in scaling observed in seismicity catalogues. The existence of the
26 theoretical kink remains however to be proven. Finally, we describe how to estimate
27 the Solid Seismicity parameters (activation density δ_+ , aftershock solid envelope r_*
28 and background stress amplitude range $\Delta\sigma_*$) for large M values.

29

30 **1. Introduction**

31 Aftershocks, one of the most studied patterns observed in seismicity, are
32 characterized by three empirical laws, which are functions of time, such as the
33 Modified Omori law (e.g., Utsu et al., 1995), space (e.g., Richards-Dinger et al., 2010;
34 Moradpour et al., 2014), and mainshock magnitude (Utsu, 1970a; b; Ogata, 1988).

35 The present study focuses on the latter relationship, i.e., the Utsu aftershock
36 productivity law, which describes the total number of aftershocks K produced by a
37 mainshock of magnitude M as
38 $K(M) = K_0 \exp[\alpha(M - m_0)]$ (1)
39 with m_0 the minimum magnitude cutoff (Utsu, 1970b; Ogata, 1988). This relationship
40 was originally proposed by Utsu (1970a; b) by combining two other empirical laws,
41 the Gutenberg-Richter relationship (Gutenberg and Richter, 1944) and Båth's law
42 (Båth, 1964), respectively:

$$43 \begin{cases} N(\geq m) = A \exp[-\beta(m - m_0)] \\ N(\geq M - \Delta m_B) = 1 \end{cases} \quad (2)$$

44 with N the number of events above magnitude m , A a seismic activity constant, β the
45 magnitude size ratio (or $b = \beta/\ln(10)$ in base-10 logarithmic scale) and Δm_B the
46 magnitude difference between the mainshock and its largest aftershock, such that
47 $K(M) = N(\geq m_0|M) = \exp(-\beta\Delta m_B) \exp[\beta(M - m_0)]$ (3)
48 with $K_0 = \exp(-\beta\Delta m_B)$ and $\alpha \equiv \beta$. Eq. (3) was only implicit in Utsu (1970a) and
49 not exploited in Utsu (1970b) where K_0 was fitted independently of the value taken by
50 Båth's parameter Δm_B . The α -value was in turn decoupled from the β -value in later
51 studies (e.g., Seif et al. (2017) and references therein).

52 Although it seems obvious that Eq. (1) can be explained geometrically if the
53 volume of the aftershock zone is correlated to the mainshock surface area S with
54 $S(M) = 10^{M-4} = \exp[\ln(10)(M - 4)]$ (4)
55 (Kanamori and Anderson, 1975; Yamanaka and Shimazaki, 1990; Helmstetter, 2003),
56 there is so far no analytical, physical expression of Eq. (1) available. Although Hainzl
57 et al. (2010) retrieved the exponential behavior in numerical simulations where
58 aftershocks were produced by the permanent static stress field of mainshocks of

59 different magnitudes, it remains unclear how K_0 and α relate to the underlying
60 physical parameters.

61 The aim of the present article is to explain the Utsu aftershock productivity
62 equation (Eq. 1) by applying a geometrical theory of seismicity (based on the Solid
63 Seismicity Postulate, SSP), which has already been shown to effectively explain other
64 empirical laws of both natural and induced seismicity from simple geometric
65 operations on a permanent static stress field (Mignan, 2012; 2016a). The theory is
66 applied here for the first time to the case of aftershocks.

67

68 **2. Physical Expression of the Aftershock Productivity Law**

69 *2.1. Demonstration of the productivity law by geometric operations*

70 “Solid Seismicity”, a geometrical theory of seismicity, is based on the
71 following Postulate (Mignan et al., 2007; Mignan, 2008, 2012; 2016a):

72

73 **Solid Seismicity Postulate (SSP):** *Seismicity can be strictly categorized*
74 *into three regimes of constant spatiotemporal densities δ – background*
75 *δ_0 , quiescence δ_- and activation δ_+ (with $\delta_- \ll \delta_0 \ll \delta_+$) - occurring*
76 *respective to the static stress step function:*

$$77 \quad \delta(\sigma) = \begin{cases} \delta_- & , \sigma < -\Delta\sigma_* \\ \delta_0 & , \sigma \leq |\pm\Delta\sigma_*| \\ \delta_+ & , \sigma > \Delta\sigma_* \end{cases} \quad (5)$$

78 *with σ the static stress [bar], $\Delta\sigma_*$ the background stress amplitude range*
79 *[bar], a stress threshold value separating two seismicity regimes, and δ*
80 *the spatial density of events [events/km³] per regime.*

81

82 We mean by “strictly categorized” that any seismicity population is either part of the
83 background, quiescence or activation regime (or class), with no other regime/class
84 possible (i.e., a sort of hard labelling). Based on this Postulate, Mignan (2012)
85 demonstrated the power-law behavior of precursory seismicity in agreement with the
86 observed time-to-failure equation (Varnes, 1989), while Mignan (2016a)
87 demonstrated both the observed parabolic spatiotemporal front and the linear
88 relationship with injection-flow-rate of induced seismicity (Shapiro and Dinske,
89 2009). It remains unclear whether the SSP has a physical origin or not. If not, it would
90 still represent a reasonable approximation of the linear relationship between event
91 production and static stress field in a simple clock-change model (Hainzl et al., 2010;
92 Fig. 1a). For the testing of the SSP on the observed spatial distribution of aftershocks,
93 see section 2.2. The power of Eq. (5) is that it allows defining seismicity patterns in
94 terms of “solids” described by the spatial envelope $r_* = r(\sigma = \pm\Delta\sigma_*)$ where r is the
95 distance from the static stress source (e.g., mainshock rupture) and r_* the distance r at
96 which there is a change of regime (quiescence/background at $\sigma = -\Delta\sigma_*$ or
97 background/activation at $\sigma = \Delta\sigma_*$). The spatiotemporal rate of seismicity is then a
98 mathematical expression defined by the density of events δ times the volume
99 characterized by r_* (see previous demonstrations in Mignan et al. (2007) and Mignan
100 (2011; 2012; 2016a) where simple algebraic expressions were obtained).

101 In the case of aftershocks, we define the static stress field of the mainshock by

$$102 \quad \sigma(r) = -\Delta\sigma_0 \left[\left(1 - \frac{c^3}{(r+c)^3} \right)^{-1/2} - 1 \right] \quad (6)$$

103 with $\Delta\sigma_0 < 0$ the mainshock stress drop, c the crack radius and r the distance from the
104 crack. Eq (6) is a simplified representation of stress change from slip on a planar
105 surface in a homogeneous elastic medium. It takes into account both the square root

106 singularity at crack tip and the $1/r^3$ falloff at higher distances (Dieterich, 1994; Fig.
 107 1b). It should be noted that this radial static stress field does not represent the
 108 geometric complexity of Coulomb stress fields (Fig. 2a). However we are here only
 109 interested in the general behavior of aftershocks with Eq. (6) retaining the first-order
 110 characteristics of this field (i.e., on-fault seismicity; Fig. 2b), which corresponds to the
 111 case where the mainshock relieves most of the regional stresses and aftershocks occur
 112 on optimally oriented faults. It is also in agreement with observations, most
 113 aftershocks being located on and around the mainshock fault traces in Southern
 114 California (Fig. 2c; see section “Observations & Model Fitting”). The occasional
 115 cases where aftershocks occur off-fault (e.g., Ross et al., 2017) can be explained by
 116 the mainshock not relieving all of the regional stress (King et al., 1994; Fig. 2d).

117 For $r_* = r(\sigma = \Delta\sigma_*)$, Eq. (6) yields the aftershock solid envelope of the form:

$$118 \quad r_*(c) = \left\{ \frac{1}{\left[1 - \left(1 - \frac{\Delta\sigma_*}{\Delta\sigma_0}\right)^{-2}\right]^{1/3}} - 1 \right\} c = Fc, \quad (7)$$

119 function of the crack radius c and of the ratio between background stress amplitude
 120 range $\Delta\sigma_*$ and stress drop $\Delta\sigma_0$ (Fig. 1c). With $\Delta\sigma_0$ independent of earthquake size
 121 (Kanamori and Anderson, 1975; Abercrombie and Leary, 1993) and $\Delta\sigma_*$ assumed
 122 constant, r_* is directly proportional to c with proportionality constant, or stress factor,
 123 F (Eq. 7). Geometrical constraints due to the seismogenic layer width w_0 then yield

$$124 \quad c(M) = \begin{cases} \left(\frac{S(M)}{\pi}\right)^{1/2} & , S(M) \leq \pi w_0^2 \\ w_0 & , S(M) > \pi w_0^2 \end{cases} \quad (8)$$

125 with S the rupture surface area defined by Eq. (4) and c becoming an effective crack
 126 radius (Kanamori and Anderson, 1975; Fig. 1d). Note that the factor of 2 (i.e., using
 127 w_0 instead of $w_0/2$) comes from the free surface effect (e.g., Kanamori and Anderson,
 128 1975; Shaw and Scholz, 2001).

129 The aftershock productivity $K(M)$ is then the activation density δ_+ times the
130 volume $V_*(M)$ of the aftershock solid. For the case in which the mainshock relieves
131 most of the regional stress, stresses are increased all around the rupture (King et al.,
132 1994), which is topologically identical to stresses increasing radially from the rupture
133 plane (Fig. 2a-b). It follows that the aftershock solid can be represented by a volume
134 of contour $r_*(M)$ from the rupture plane geometric primitive, i.e., a disk or a
135 rectangle, for small and large mainshocks, respectively. This is illustrated in Figure
136 3a-b and can be generalized by

$$137 \quad V_*(M) = 2r_*(M)S(M) + \frac{\pi}{2}r_*^2(M)d \quad (9)$$

138 where d is the distance travelled around the geometric primitive by the geometric
139 centroid of the semi-circle of radius $r_*(M)$ (i.e., Pappus's Centroid Theorem), or

$$140 \quad d = \begin{cases} 2\pi \left(c(M) + \frac{4}{3\pi} r_*(M) \right) & , c(M) + r_*(M) \leq \frac{w_0}{2} \\ 2w_0 & , c(M) + r_*(M) > \frac{w_0}{2} \end{cases} \quad (10)$$

141 For the disk, the volume (Eq. 9) corresponds to the sum of a cylinder of radius $c(M)$
142 and height $2r_*(M)$ (first term) and of half a torus of major radius $c(M)$ and minus
143 radius $r_*(M)$ (second term). For the rectangle, the volume is the sum of a cuboid of
144 length $l(M)$ (i.e., rupture length), width w_0 and height $2r_*(M)$ (first term) and of a
145 cylinder of radius $r_*(M)$ and height w_0 (second term; see red and orange volumes,
146 respectively, in Figure 3a-c). Finally inserting Eqs. (7), (8) and (10) into (9), we
147 obtain

$$148 \quad K(M) = \delta_+ \begin{cases} \left[\frac{2F}{\sqrt{\pi}} + F^2\sqrt{\pi} \left(1 + \frac{4}{3\pi} F \right) \right] S^{3/2}(M) & , S(M) \leq \left(\frac{w_0\sqrt{\pi}}{2(1+F)} \right)^2 \\ \frac{2F}{\sqrt{\pi}} S^{3/2}(M) + F^2 w_0 S(M) & \left(\frac{w_0\sqrt{\pi}}{2(1+F)} \right)^2 < S(M) \leq \pi w_0^2 \\ 2F w_0 S(M) + \pi F^2 w_0^3 & , S(M) > \pi w_0^2 \end{cases}$$

$$149 \quad (11)$$

150 which is represented in Figure 3d. Considering the two main regimes only (small
 151 versus large mainshocks) and inserting Eq. (4) into (11), we get

$$152 \quad K(M) = \delta_+ \begin{cases} \left[\frac{2F}{\sqrt{\pi}} + F^2 \sqrt{\pi} \left(1 + \frac{4}{3\pi} F \right) \right] \exp \left[\frac{3\ln(10)}{2} (M - 4) \right] & , \text{small } M \\ 2Fw_0 \exp[\ln(10)(M - 4)] + \pi F^2 w_0^3 & , \text{large } M \end{cases} \quad (12)$$

153 which is a closed-form expression of the same form as the original Utsu productivity
 154 law (Eq. 1). Note that K and δ_+ are both, implicitly, function of the selected minimum
 155 aftershock magnitude threshold m_0 .

156 Here, we predict that the α -value decreases from $3\ln(10)/2 \approx 3.45$ to $\ln(10) \approx$
 157 2.30 when switching regime from small to large mainshocks (or from 1.5 to 1 in base-
 158 10 logarithmic scale). It should be noted that Hainzl et al. (2010) observed the same
 159 break in scaling in static stress transfer simulations, which corroborates our analytical
 160 findings. Hainzl et al. (2010) simulated aftershocks using the clock-change model
 161 where events were advanced in time by the static stress change produced by a
 162 mainshock in a three-dimensional medium. They explained the scaling break
 163 observed in simulation as a transition from 3D to 2D scaling regime when the
 164 mainshock rupture dimension approached w_0 , which is compatible with the present
 165 demonstration. For large M , the scaling is fundamentally the same as in Eq. (4). Since
 166 that relation also explains the slope of the Gutenberg-Richter law (see physical
 167 explanation given by Kanamori and Anderson, 1975), it follows that $\alpha \equiv \beta$, which is
 168 also in agreement with the original formulation of Utsu (1970a; b; Eq. 3).

169

170 *2.2. Testing of the SSP on the aftershock spatial distribution*

171 The SSP predicts a step-like behavior of the aftershock spatial density for an
 172 idealized smooth static stress field (Fig. 4a-b), which is in disagreement with real

173 aftershock observations. A number of studies have shown that the spatial linear
174 density distribution of aftershocks ρ is well represented by a power-law, expressed as
175 $\rho(r) \propto r^{-q}$ (13)
176 with r the distance from the mainshock and q the power-law exponent. This parameter
177 ranges over $1.3 \leq q \leq 2.5$ (Felzer and Brodsky, 2006; Lipiello et al., 2009; Marsan and
178 Lengliné, 2010; Richards-Dinger et al., 2010; Shearer, 2012; Gu et al., 2013;
179 Moradpour et al., 2014; van der Elst and Shaw, 2015). Although Felzer and Brodsky
180 (2004) suggested a dynamic stress origin for aftershocks, their results were later on
181 questioned by Richards-Dinger et al. (2010). Most of the studies cited above suggest
182 that the q -value is explained from a static stress process. As for the examples of
183 aftershocks shown to be dynamically triggered (e.g., Fan and Shearer, 2016), they are
184 too few to alter the aftershock productivity law and too remote to be consistently
185 defined as aftershocks in cluster methods.

186 In a more realistic setting, the static stress field must be heterogeneous (due to
187 the occurrence of previous events and other potential stress perturbations). We
188 therefore simulate the static stress field by adding a uniform random component
189 bounded over $\pm\Delta\sigma_*$ following Mignan (2011) (see also King and Bowman, 2003).
190 Note that any deviation above $\Delta\sigma_*$ would be flattened to $\Delta\sigma_*$ over time by temporal
191 diffusion (so-called “historical ghost static stress field” in Mignan, 2016a). Figure 4c
192 shows the resulting stress field and Figure 4d the predicted aftershock spatial density.
193 Adding uniform noise blurs the contour of the aftershock solid, switching the
194 aftershock spatial density from a step function (Fig. 4b) to a power-law (Fig. 4d). We
195 fit Eq. (13) to the simulated data using the Maximum Likelihood Estimation (MLE)
196 method with $r_{min} = r_*$ (Clauset et al., 2009) and find $q = 1.96 \pm 0.01$, in agreement with

197 the aftershock literature. This result alone is however insufficient to prove the validity
198 of the SSP.

199

200 **3. Observations & Model Fitting**

201 *3.1. Data*

202 We consider the case of Southern California and extract aftershock sequences
203 from the relocated earthquake catalog of Hauksson et al. (2012) defined over the
204 period 1981-2011, using the nearest-neighbor method (Zaliapin et al., 2008; used with
205 its standard parameters originally calibrated for Southern California, considering only
206 the first aftershock generation). Only events with magnitudes greater than $m_0 = 2.0$ are
207 considered (a conservative estimate following results of Tormann et al. (2014);
208 saturation effects immediately after the mainshock are negligible when considering
209 entire aftershock sequences; Helmstetter et al., 2005).

210

211 *3.2. Aftershock spatial density distribution*

212 Figure 5a represents the spatial linear density distribution of aftershocks $\rho(r)$
213 for the four largest strike-slip mainshocks in Southern California: 1987 $M=6.6$
214 Superstition Hills, 1992 $M=7.3$ Landers, 1999 $M=7.1$ Hector Mine, and 2010 $M=7.2$
215 El Mayor. The distance between mainshock and aftershocks is calculated as
216 $r = \sqrt{(x - x_0)^2 + (y - y_0)^2}$ with (x, y) the aftershock coordinates and (x_0, y_0) the
217 coordinates of the nearest point to the mainshock fault rupture (as depicted in Figure
218 2c). The dashed black lines shown in Figure 5a are visual guides to $q = 1.96$, showing
219 that the SSP is compatible with real aftershock observations.

220 Comparing Figure 5a to Figure 4d suggests that r_* can be roughly estimated
221 from the spatial linear density plot, being the maximum distance r at which the

222 plateau ends, here leading to $r_* \approx 1$ km. This parameter is constant for different large
 223 M values since both w_0 and $\Delta\sigma_0$ are constant while $\Delta\sigma_*$ is also *a priori* a constant. We
 224 can then estimate the ratio $\Delta\sigma_*/\Delta\sigma_0$ from Eq. (7). However the result is ambiguous
 225 due to uncertainties on the width w_0 . For $w_0 = \{5, 10, 15\}$ km, we get $\Delta\sigma_*/\Delta\sigma_0 = \{-$
 226 $0.54, -1.01, -1.38\}$.

227 As for the plateau value $\rho(r < r_*)$, it provides an estimate of the aftershock
 228 activation density δ_+ with

$$229 \quad \delta_+ = \frac{\rho(M, r < r_*)}{\exp[\ln(10)(M-4)]} \quad (14)$$

230 a volumetric density, i.e. the linear density ρ normalized by the mainshock rupture
 231 area (Eq. 4). Due to the fluctuations in $\rho(r < r_*)$, δ_+ will be estimated from the
 232 productivity law instead (see section 3.3) and $\rho(r < r_*)$ then estimated from Eq. (14)
 233 (horizontal dashed colored lines), as detailed below.

234 It should be noted that we consider only the first-generation aftershocks to
 235 avoid ρ heterogeneities from secondary aftershock clusters occurring off-fault. An
 236 example of such heterogeneity/anisotropy is illustrated by the Landers-Big Bear case
 237 (Fig. 2c; dotted colored curve on Fig. 5a). Those cases are not systematic and
 238 therefore not considered in the aftershock productivity law. However they are also
 239 due to static stress changes (e.g., King et al., 1994) with the anisotropic effects
 240 explainable by Solid Seismicity through the concept of “historical ghost static stress
 241 field” (Mignan, 2016a).

242

243 3.3. Aftershock productivity law

244 The observed number n of aftershocks of magnitude $m \geq m_0$ produced by a
 245 mainshock of magnitude M (for a total of N mainshocks) in Southern California is

246 shown in Figures 5b (for large $M \geq 6$) and 6a (for the full range $M \geq m_0$). We fit Eq.

247 (1) to the data using the MLE method with the log-likelihood function

$$248 \quad LL(\theta; X = \{n_i; i = 1, \dots, N\}) = \sum_{i=1}^N [n_i \ln[K_i(\theta)] - K_i(\theta) - \ln(n_i!)] \quad (15)$$

249 for a Poisson process, representing the stochasticity of the count K of aftershocks

250 produced by a mainshock at any given time. Inserting Eq. (1) in Eq. (15) yields

$$251 \quad LL(\theta = \{K_0, \alpha\}; X) = \ln(K_0) \sum_{i=1}^N n_i + \alpha \sum_{i=1}^N [n_i (M_i - m_0)] - K_0 \sum_{i=1}^N \exp[\alpha (M_i - \\ 252 \quad m_0)] - \sum_{i=1}^N \ln(n_i!) \quad (16)$$

253 (note that the last term can be set to 0 during LL maximization). For Southern

254 California, we obtain $\alpha_{MLE} = 2.32$ (1.01 in \log_{10} scale) and $K_0 = 0.025$ when

255 considering large $M \geq 6$ mainshocks only to avoid the issues of scaling break and data

256 dispersion at lower magnitudes. This result, represented by the black solid line on

257 Figure 5b, is in agreement with previous studies in the same region (e.g., Helmstetter,

258 2003; Helmstetter et al., 2005; Zaliapin and Ben-Zion, 2013; Seif et al., 2017) and

259 with $\alpha = \ln(10) \approx 2.30$ predicted for large mainshocks in Solid Seismicity (Eq. 12).

260 Moreover we find a bulk $\beta_{MLE} = 2.34$ (1.02 in \log_{10} scale) (Aki, 1965), in agreement

261 with $\alpha \equiv \beta$.

262 Let us now rewrite the Solid Seismicity aftershock productivity law (Eq. 12)

263 by only considering the large M case and injecting $r_* = F w_0$ (by combining Eqs. 7-8).

264 We get

$$265 \quad K(M > M_{break}) = \delta_+ \{2r_* \exp[\ln(10)(M - 4)] + \pi r_*^2 w_0\} \quad (17)$$

266 The role of w_0 is illustrated in Figure 5b for different values (dashed and dotted

267 curves) and shown to be insignificant for large M values. Therefore Eq. (17) can be

268 approximated to

$$269 \quad K(M > M_{break}) \approx 2\delta_+ r_* \exp[\ln(10)(M - 4)] \quad (18)$$

270 By analogy with Eq. (1), we get

271
$$\delta_+ = \frac{K_0 \exp[\ln(10)(4-m_0)]}{2r_*} \quad (19)$$

272 With $r_* \approx 1$ km estimated from $\rho(r)$ (section 3.2) and $K_0 = 0.025$, we obtain $\delta_+ = 1.23$
 273 events/km³ for $m_0 = 2$. We then get back the plateau $\rho(r < r_*)$ for different M values
 274 from Eq. (14), as shown in Figure 5a (horizontal dashed colored lines). Although
 275 based on limited data, this result suggests that the activation parameter δ_+ is constant
 276 (at least for large M) in Southern California. Note that if $\rho(r < r_*)$ was well
 277 constrained, it could have been estimated jointly with r_* from Figure 5a to predict the
 278 aftershock productivity law of Figure 5b without further fitting required (hence
 279 removing K_0 from the equation, K_0 having no physical meaning in Solid Seismicity).

280

281 **4. Role of aftershock selection on productivity scaling-break**

282 We tested the following piecewise model to identify any break in scaling at
 283 smaller M , as predicted by Eq. (12):

284
$$K(M) = \begin{cases} K_0 \frac{\exp[\ln(10)(M_{break}-m_0)]}{\exp[\frac{3}{2}\ln(10)(M_{break}-m_0)]} \exp\left[\frac{3}{2}\ln(10)(M-m_0)\right] & , M \leq M_{break} \\ K_0 \exp[\ln(10)(M-m_0)] & , M > M_{break} \end{cases}$$

285 (20)

286 but with the best MLE result obtained for $M_{break} = m_0$, suggesting no break in scaling
 287 in the aftershock productivity data, as observed in Figure 6a. Final parameter
 288 estimates are $\alpha_{MLE} = 1.95$ (0.85 in log₁₀ scale) and $K_0 = 0.141$ for the full mainshock
 289 magnitude range $M \geq m_0$ (dotted line), subject to high scattering at low M values.

290 We now identify whether the lack of break in scaling in aftershock
 291 productivity observed in earthquake catalogues could be an artefact related to the
 292 aftershock selection method. We run Epidemic-Type Aftershock Sequence (ETAS)
 293 simulations (Ogata, 1988; Ogata and Zhuang, 2006), with the seismicity rate

$$\begin{cases}
\lambda(t, x, y) = \mu(t, x, y) + \sum_{i:t_j < t} K(M_i) f(t - t_i) g(x - x_i, y - y_i | M_i) \\
f(t) = c^{p-1} (p - 1) (t + c)^{-p} \\
g(x, y | M) = \frac{1}{\pi} (d e^{\gamma(M-m_0)})^{q-1} (x^2 + y^2 + d e^{\gamma(M-m_0)})^{-q} (q - 1)
\end{cases} \quad (21)$$

295 Aftershock sequences are defined by power laws, both in time and space (for an
296 alternative temporal function, see Mignan (2015; 2016b); the spatial power-law
297 distribution is in agreement with Solid Seismicity in the case of a heterogeneous static
298 stress field – see section 2.2). μ is the Southern California background seismicity, as
299 defined by the nearest-neighbor method (with same t, x, y and m). We fix the ETAS
300 parameters to $\theta = \{c = 0.011 \text{ day}, p = 1.08, d = 0.0019 \text{ km}^2, q = 1.47, \gamma = 2.01, \beta =$
301 $2.29, K_0 = 0.08\}$, following the fitting results of Seif et al. (2017) for the Southern
302 California relocated catalog and $m_0 = 2$ (see their Table 1). However, we define the
303 productivity function $K(M)$ from Eq. (20) with $M_{break} = 5$. Examples of ETAS
304 simulations are shown in Figure 6b for comparison with the observed Southern
305 California time series. Figure 6c allows us to verify that the simulated aftershock
306 productivity is kinked at M_{break} , as defined by Eq. (20).

307 We then select aftershocks from the ETAS simulations with the nearest-
308 neighbor method. Figure 4d represents the estimated aftershock productivity, which
309 has lost the break in scaling originally implemented in the simulations (with an
310 underestimated $\alpha_{MLE} = 2.07$ as observed in the real case for $M \geq m_0$). Note that a
311 similar result is obtained when using a windowing method (Gardner and Knopoff,
312 1974). This demonstrates that the theoretical break in scaling predicted in the
313 aftershock productivity law can be lost in observations due to an aftershock selection
314 bias, all declustering techniques assuming continuity over the entire magnitude range.
315 While such a bias is possible, it yet does not prove that the break in scaling exists. The
316 fact that a similar break in scaling was obtained in independent Coulomb stress
317 simulations (Hainzl et al., 2010) however provides high confidence in our results.

318 One other possible explanation for lack of scaling break is that our
319 demonstration assumes moment magnitudes while the Southern California catalogue
320 is in local magnitudes. Deichmann (2017) demonstrated that while $M_L \propto M_w$ at large
321 M , $M_L \propto 1.5M_w$ at smaller M values. This could in theory cancel the kink in real data.
322 However the scaling break predicted by Deichmann (2017) occurs at several
323 magnitude units below the geometric scaling break expected by Solid Seismicity,
324 invalidating this second option for mid-range magnitudes M .

325

326 **5. Conclusions**

327 In the present study, a closed-form expression defined from geometric and
328 static stress parameters was proposed (Eq. 12) to explain the empirical Utsu
329 aftershock productivity law (Eq. 1). This demonstration is similar to the previous ones
330 made by the author to explain precursory accelerating seismicity and induced
331 seismicity (Mignan, 2012; 2016b). In all these demonstrations, the main physical
332 parameters remain the same, i.e. the activation density δ_+ (also δ_- and δ_0), the
333 background stress amplitude range $\Delta\sigma_*$, and the solid envelope r_* which describes the
334 geometry of the “seismicity solid” (Fig. 3a-b). Further studies will be needed to
335 evaluate whether the δ_+ and $\Delta\sigma_*$ parameters are universal or region-specific and if the
336 same values apply to different types of seismicity at a same location.

337 Although the Solid Seismicity Postulate (SSP) (Eq. 5) remains to be proven, it
338 is so far a rather convenient and pragmatic assumption to determine the physical
339 parameters that play a first-order role in the behavior of seismicity. The similarity of
340 the SSP-simulated and observed values of the power-law exponent q of the aftershock
341 spatial density distribution shows that the SSP is consistent with large aftershock
342 observations once uniform noise is added to the stress field (Figs. 4d-5a). The impact

343 of other types of noise on q has yet to be investigated. The SSP is also complementary
344 to the more common simulations of static stress loading (King and Bowman, 2003)
345 and static stress triggering (Hainzl et al., 2010).

346 Analytic geometry, providing both a visual representation and an analytical
347 expression of the problem at hand (Fig. 3), represents a new approach to try to better
348 understand the behavior of seismicity. Its current limitation in the case of aftershock
349 analysis consists in assuming that the static stress field is radial and described by Eq.
350 (6) (e.g., Dieterich, 1994), which is likely only valid for mainshocks relieving most of
351 the regional stresses and with aftershocks occurring on optimally oriented faults (King
352 et al., 1994). More complex, second-order, stress behaviors might explain part of the
353 scattering observed around Eq. (1) (Fig. 6a), such as overpressure due to trapped high-
354 pressure gas for example (Miller et al., 2004 – see also Mignan (2016a) for an
355 overpressure field due to fluid injection). Other $\sigma(r)$ formulations could be tested in
356 the future, the only constraint on generating so-called seismicity solids being the use
357 of the postulated static stress step function of Eq. (5) (i.e., the Solid Seismicity
358 Postulate, SSP).

359 Finally, the disappearance of the predicted scaling break in the aftershock
360 productivity law once declustering is applied (Fig. 6) indicates that more work is
361 required in that domain. Only a declustering technique that does not dictate a constant
362 scaling at all M will be able to identify rather a scaling break really exists or not.

497

498 **Figure 1.** Definition of the aftershock solid envelope in a permanent static stress field:

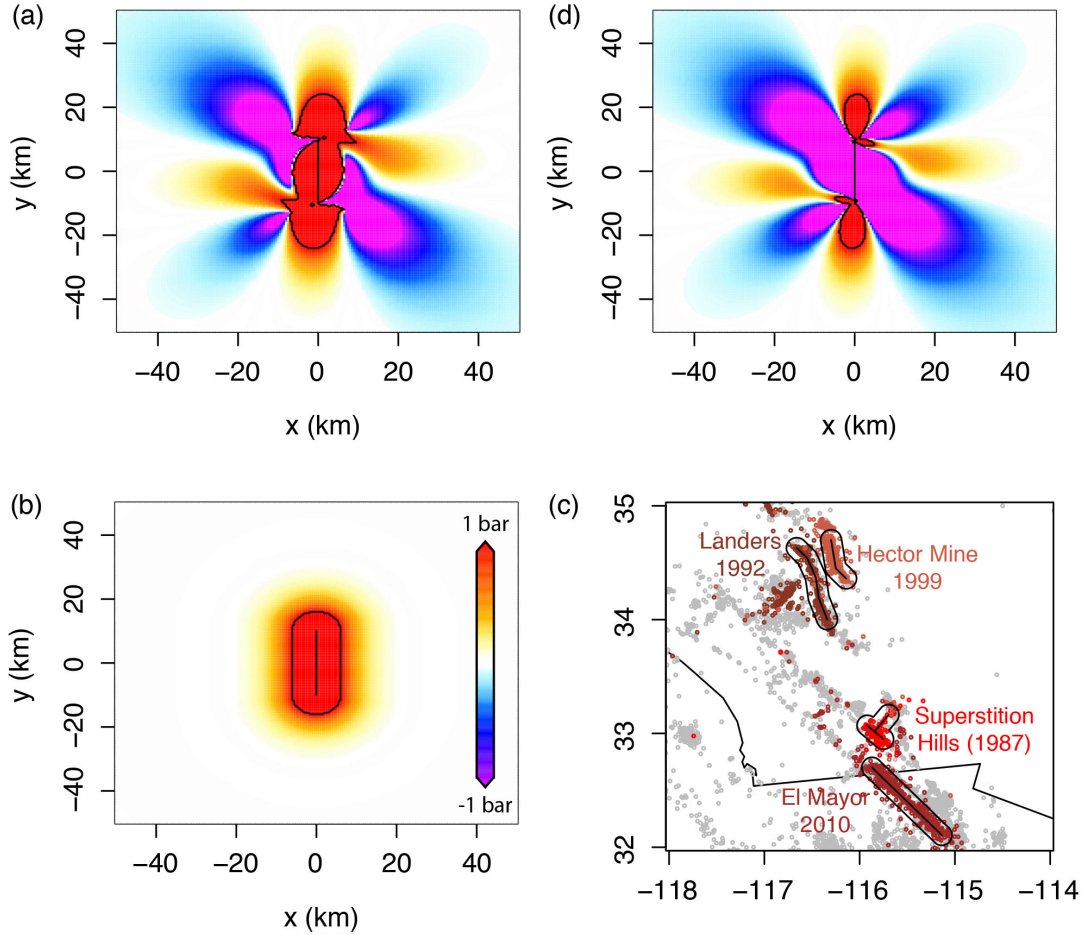

499 (a) Event density stress step-function $\delta(\sigma)$ (Eq. 5) of the Solid Seismicity Postulate

500 (SSP) in comparison to the linear clock-change model; (b) Static stress σ versus

501 distance r for different effective crack radii c and rupture stress drops $\Delta\sigma_0$ (Eq. 6); (c)

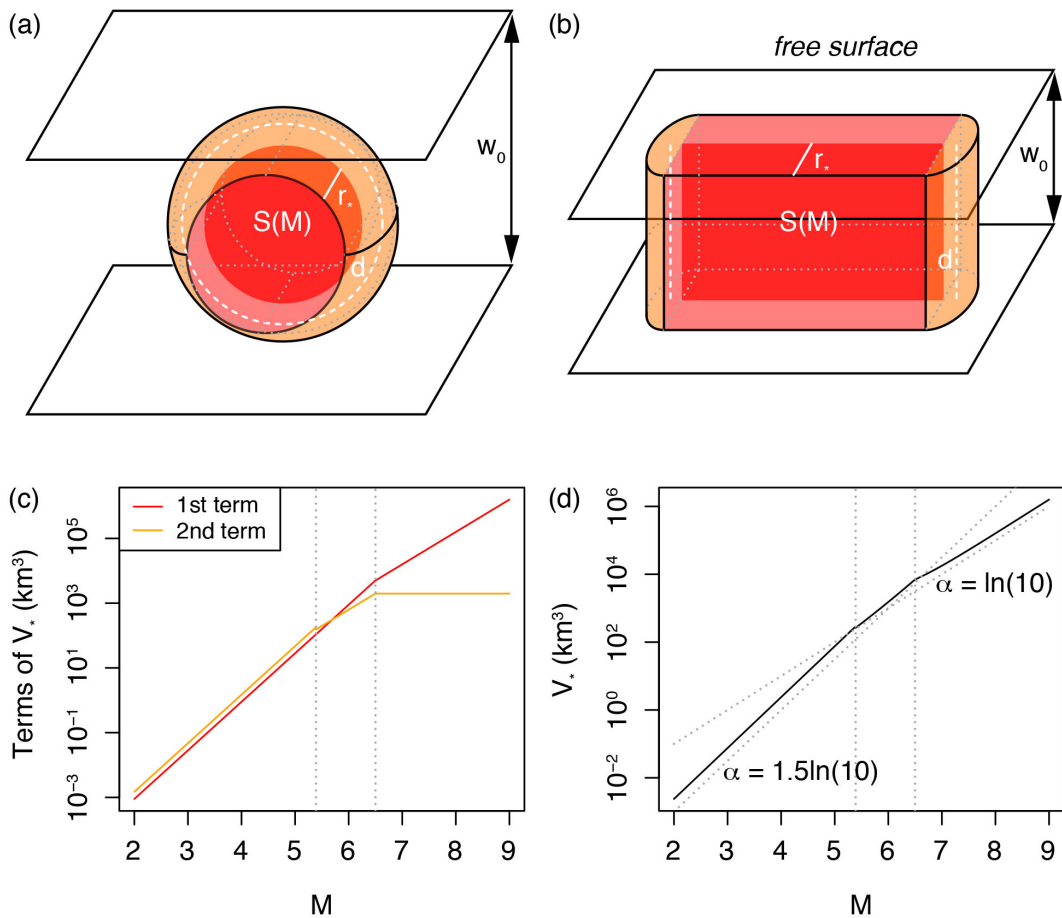

502 Linear relationship between effective crack radius c and aftershock solid envelope

503 radius r_* for different $\Delta\sigma_*/\Delta\sigma_0$ ratios (Eq. 7); (d) Relationship between mainshock
 504 magnitude M and effective crack radius c for different seismogenic widths w_0 (Eq. 8).
 505

506
 507 **Figure 2.** Possible static stress fields and inferred aftershock spatial distribution: (a)
 508 Right-lateral Coulomb stress field for optimally oriented faults, where the mainshock
 509 relieves all of the regional stresses $\sigma_r = 10$ bar, with $\Delta\sigma_0 \approx -Gs/L \approx -10$ bar ($G =$
 510 $3.3 \cdot 10^5$ bar the shear modulus, $s = 0.6$ m the slip, $L = 20$ km the fault length, and $w =$
 511 10 km the fault width); (b) Radial static stress field computed from Eq. (6) with $\Delta\sigma_0 =$
 512 -10 bar and $c = \sqrt{(Lw)/\pi}$ for consistency with (a); (c) Aftershock distribution of the
 513 largest strike-slip events in the Southern California relocated catalog, identified here
 514 as all events occurring within one day of the mainshock (see Data section 3.1); (d)

515 Right-lateral Coulomb stress field for optimally oriented faults, where the mainshock
 516 relieves only a fraction of the regional stresses $\sigma_r = 100$ bar with $\Delta\sigma_0 = -10$ bar (same
 517 rupture as in (a)) – The black contour represents 1 bar in (a), (b) and (d), and a 10 km
 518 distance from rupture in (c). Coulomb stress fields of (a) and (d) were computed using
 519 the Coulomb 3 software (Lin and Stein, 2004; Toda et al., 2005).
 520

521
 522 **Figure 3.** Geometric origin of the aftershock productivity law: (a) Sketch of the
 523 aftershock solid for a small mainshock rupture represented by a disk; (b) Sketch of the
 524 aftershock solid for a large mainshock rupture represented by a rectangle; (c) Relative
 525 role of the two terms of Eq. (9), here with $w_0 = 10$ km and $\frac{\Delta\sigma_*}{\Delta\sigma_0} = -0.1$ (to first estimate
 526 c and r_* from Eqs. 8 and 7, respectively); (d) Aftershock productivity law (normalized
 527 by δ_+) predicted by Solid Seismicity (Eq. 11). This relationship is of the same form as

528 the Utsu productivity law (Eq. 1) for large M (see text for an explanation of the lack
 529 of break in scaling in Eq. 1 for small M). Dotted vertical lines represent M for
 530 $c(M) + r_*(M) = \frac{w_0}{2}$ and $S(M) = \pi w_0^2$, respectively.

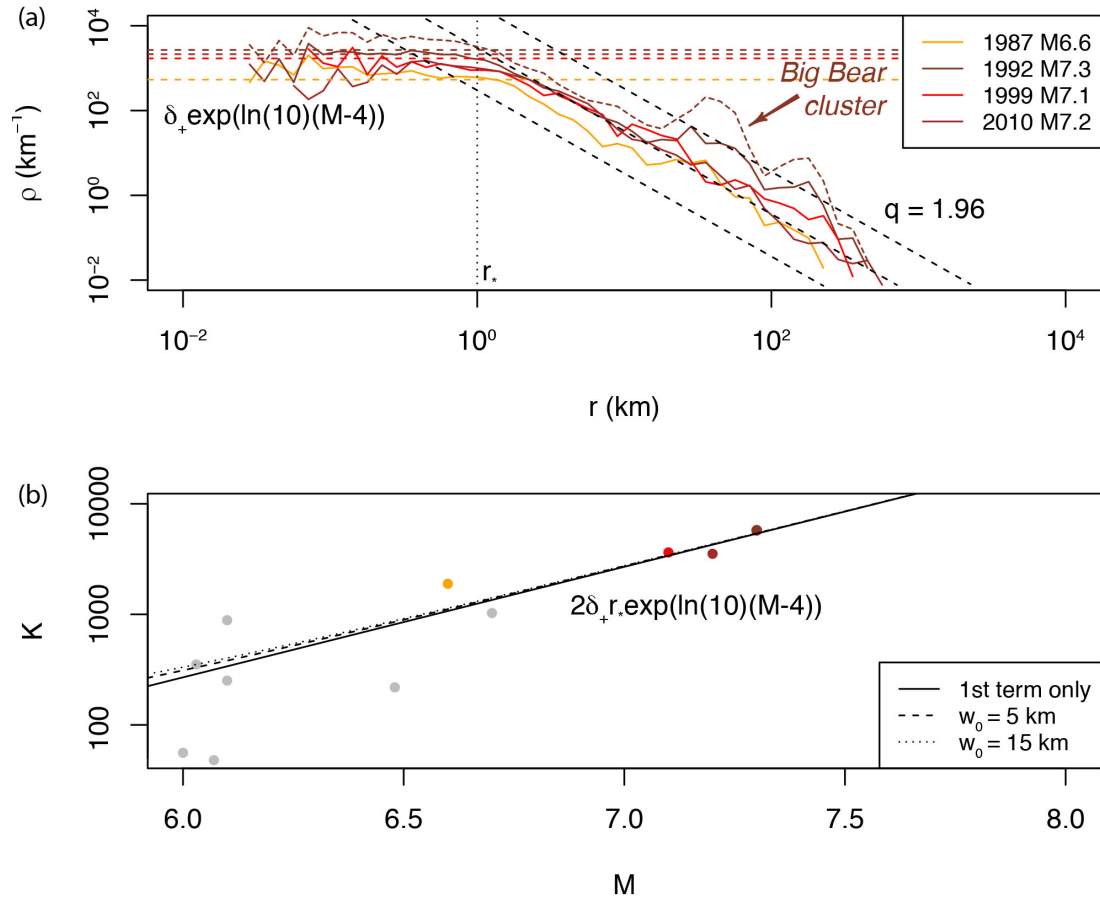

531

532

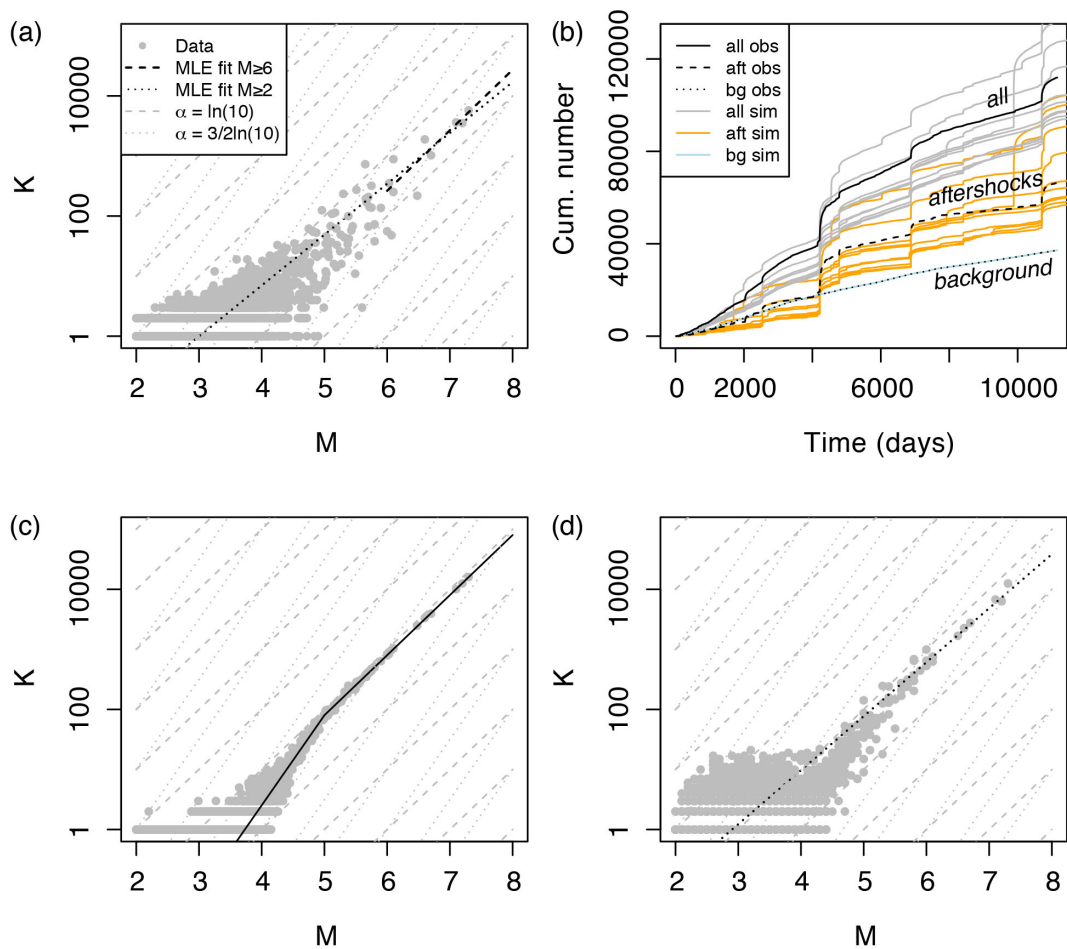

533 **Figure 4.** Spatial distribution of aftershocks following the SSP. (a) Smooth static
 534 stress field as a function of distance r from the mainshock, with $\Delta\sigma_0 = -10$ bar and $c =$
 535 10 km (Eq. 6); (b) Step-like aftershock spatial linear density $\rho(r)$ with $\delta_+ = 1000$
 536 events per km, $\delta_0 = 1$ event per km and $\Delta\sigma_* = -0.3\Delta\sigma_0$ (*ad-hoc* ratio yielding $r_* = 3.5$
 537 km; Eq. (7) – event distances sampled from the $\delta(r)$ distribution, repeated 100 times).
 538 Such distribution is not observed in Nature; (c) Same as (a) but with random uniform
 539 noise representative of spatial heterogeneities added to the regional stress field; (d)

540 Power-law-like aftershock spatial linear density $\rho(r)$ with power exponent MLE
 541 estimate $q = 1.96$, representative of real aftershock observations (see Fig. 5a), due to
 542 the addition of uniform noise to the static stress field.
 543

544
 545 **Figure 5.** Estimating the Solid Seismicity parameters from the spatial distribution of
 546 aftershocks: (a) Spatial linear density distribution $\rho(r)$ of aftershocks for the four
 547 largest strike-slip mainshocks in Southern California (with first-generation
 548 aftershocks only; the density distribution comprising all aftershocks generated by the
 549 Landers mainshock is represented by the dotted curve to illustrate the type of spatial
 550 heterogeneity, such as the Big Bear cluster, not considered in the present study – see
 551 also Fig. 2c). The Solid Seismicity parameters $r_* = 1$ km and $\delta_+(m_0 = 2) = 1.23$
 552 events/ km^3 can be retrieved from the observed plateau $\rho(r < r_*)$, in agreement with the

553 SSP (see Fig. 4d). Note that the spatial power-law decay at high r is similar to the one
 554 expected by the SSP in the case of a static stress field with additive uniform noise
 555 (expected $q = 1.96$ represented by the dashed black lines); (b) Aftershock productivity
 556 K for $M > 6$. The curves represent the productivity law as defined by Solid Seismicity
 557 (Eq. 17) for different w_0 values (first term only corresponds to $w_0 = 0$; Eq. 18).
 558

559
 560 **Figure 6.** Aftershock productivity defined as the number of aftershocks $K(m_0 = 2)$ per
 561 mainshock of magnitude M : (a) Observed aftershock productivity in Southern
 562 California with aftershocks selected using the nearest-neighbor method; (b)
 563 Seismicity time series with distinction made between background events and
 564 aftershocks, observed (“obs”, in black) and ETAS-simulated (“sim”, colored); (c)

565 True simulated aftershock productivity with kink, defined from Eq. (20); (d)
566 Retrieved simulated aftershock productivity with aftershocks selected using the
567 nearest-neighbor method - Data points in (a), (c) and (d) are represented by grey dots;
568 the model MLE fits are represented by the dashed and dotted black lines for $M \geq 6$
569 and $M \geq m_0$, respectively; dashed and dotted grey lines are visual guides to $\alpha =$
570 $3/2\ln(10)$ and $\ln(10)$, respectively.
