9

10 *Abstract:* The aftershock productivity law is an exponential function of the form  
11  $K \propto \exp(\alpha M)$  with  $K$  the number of aftershocks triggered by a given mainshock of  
12 magnitude  $M$  and  $\alpha \approx \ln(10)$  the productivity parameter. This law remains empirical  
13 in nature although it has also been retrieved in static stress simulations. Here, we  
14 parameterize this law using the Solid Seismicity Postulate (SSP), the basis of a  
15 geometrical theory of seismicity where seismicity patterns are described by  
16 mathematical expressions obtained from geometric operations on a permanent static  
17 stress field. We first test the SSP that relates seismicity density to a static stress step  
18 function. We show that it yields a power exponent  $q = 1.96 \pm 0.01$  for the power-law  
19 spatial linear density distribution of aftershocks, once uniform noise is added to the  
20 static stress field, in agreement with observations. We then recover the exponential  
21 function of the productivity law with a break in scaling obtained between small and  
22 large  $M$ , with  $\alpha = 1.5\ln(10)$  and  $\ln(10)$ , respectively, in agreement with results from  
23 previous static stress simulations. Possible biases of aftershock selection, verified to  
24 exist in Epidemic-Type Aftershock Sequence (ETAS) simulations, may explain the  
25 lack of break in scaling observed in seismicity catalogues. The existence of the  
26 theoretical kink remains however to be proven. Finally, we describe how to estimate  
27 the Solid Seismicity parameters (activation density  $\delta_+$ , aftershock solid envelope  $r_*$   
28 and background stress amplitude range  $\Delta\sigma_*$ ) for large  $M$  values.

29

## 30 **1. Introduction**

31 Aftershocks, one of the most studied patterns observed in seismicity, are  
32 characterized by three empirical laws, which are functions of time, such as the  
33 Modified Omori law (e.g., Utsu et al., 1995), space (e.g., Richards-Dinger et al., 2010;  
34 Moradpour et al., 2014), and mainshock magnitude (Utsu, 1970a; b; Ogata, 1988).

35 The present study focuses on the latter relationship, i.e., the Utsu aftershock  
 36 productivity law, which describes the total number of aftershocks  $K$  produced by a  
 37 mainshock of magnitude  $M$  as  
 38  $K(M) = K_0 \exp[\alpha(M - m_0)]$  (1)  
 39 with  $m_0$  the minimum magnitude cutoff (Utsu, 1970b; Ogata, 1988). This relationship  
 40 was originally proposed by Utsu (1970a; b) by combining two other empirical laws,  
 41 the Gutenberg-Richter relationship (Gutenberg and Richter, 1944) and Båth's law  
 42 (Båth, 1964), respectively:

$$43 \begin{cases} N(\geq m) = A \exp[-\beta(m - m_0)] \\ N(\geq M - \Delta m_B) = 1 \end{cases} \quad (2)$$

44 with  $N$  the number of events above magnitude  $m$ ,  $A$  a seismic activity constant,  $\beta$  the  
 45 magnitude size ratio (or  $b = \beta/\ln(10)$  in base-10 logarithmic scale) and  $\Delta m_B$  the  
 46 magnitude difference between the mainshock and its largest aftershock, such that  
 47  $K(M) = N(\geq m_0 | M) = \exp(-\beta \Delta m_B) \exp[\beta(M - m_0)]$  (3)  
 48 with  $K_0 = \exp(-\beta \Delta m_B)$  and  $\alpha \equiv \beta$ . Eq. (3) was only implicit in Utsu (1970a) and  
 49 not exploited in Utsu (1970b) where  $K_0$  was fitted independently of the value taken by  
 50 Båth's parameter  $\Delta m_B$ . The  $\alpha$ -value was in turn decoupled from the  $\beta$ -value in later  
 51 studies (e.g., Seif et al. (2017) and references therein).

52 Although it seems obvious that Eq. (1) can be explained geometrically if the  
 53 volume of the aftershock zone is correlated to the mainshock surface area  $S$  with  
 54  $S(M) = 10^{M-4} = \exp[\ln(10)(M - 4)]$  (4)  
 55 (Kanamori and Anderson, 1975; Yamanaka and Shimazaki, 1990; Helmstetter, 2003),  
 56 there is so far no analytical, physical expression of Eq. (1) available. Although Hainzl  
 57 et al. (2010) retrieved the exponential behavior in numerical simulations where  
 58 aftershocks were produced by the permanent static stress field of mainshocks of

59 different magnitudes, it remains unclear how  $K_0$  and  $\alpha$  relate to the underlying  
60 physical parameters.

61 The aim of the present article is to describe the Utsu aftershock productivity  
62 equation (Eq. 1) in terms of a geometrical theory of seismicity coined “Solid  
63 Seismicity”, where the Eq. (4) scaling is parameterized using the Solid Seismicity  
64 Postulate (SSP). The SSP has already been shown to effectively explain other  
65 empirical laws of both natural and induced seismicity from simple geometric  
66 operations on a permanent static stress field (Mignan, 2012; 2016a). The theory is  
67 applied here for the first time to describe aftershocks.

68

## 69 **2. Physical Expression of the Aftershock Productivity Law**

### 70 *2.1. Demonstration of the productivity law by geometric operations*

71 “Solid Seismicity”, a geometrical theory of seismicity, is based on the  
72 following Postulate (Mignan et al., 2007; Mignan, 2008, 2012; 2016a):

73

74 **Solid Seismicity Postulate (SSP):** *Seismicity can be strictly categorized*  
75 *into three regimes of constant spatiotemporal densities  $\delta$  – background*  
76  *$\delta_0$ , quiescence  $\delta_-$  and activation  $\delta_+$  (with  $\delta_- \ll \delta_0 \ll \delta_+$ ) - occurring*  
77 *respective to the static stress step function:*

$$78 \quad \delta(\sigma) = \begin{cases} \delta_- & , \sigma < -\Delta\sigma_* \\ \delta_0 & , \sigma \leq |\pm\Delta\sigma_*| \\ \delta_+ & , \sigma > \Delta\sigma_* \end{cases} \quad (5)$$

79 *with  $\sigma$  the static stress [stress unit],  $\Delta\sigma_*$  the background stress amplitude*  
80 *range [stress unit], a stress threshold value separating two seismicity*  
81 *regimes, and  $\delta$  the spatial density of events [number of events per unit of*  
82 *volume] per seismicity regime.*

83

84 We mean by “strictly categorized” that any seismicity population is either part of the  
85 background, quiescence or activation regime (or class), with no other regime/class  
86 possible (i.e., a sort of hard labelling). Based on this Postulate, Mignan (2012)  
87 demonstrated the power-law behavior of precursory seismicity in agreement with the  
88 observed time-to-failure equation (Varnes, 1989), while Mignan (2016a)  
89 demonstrated both the observed parabolic spatiotemporal front and the linear  
90 relationship with injection-flow-rate of induced seismicity (Shapiro and Dinske,  
91 2009). It remains unclear whether the SSP has a physical origin or not. If not, it would  
92 still represent a reasonable approximation of the linear relationship between event  
93 production and static stress field in a simple clock-change model (Hainzl et al., 2010;  
94 Fig. 1a). For the testing of the SSP on the observed spatial distribution of aftershocks,  
95 see section 2.2. The power of Eq. (5) is that it allows defining seismicity patterns in  
96 terms of “solids” described by the spatial envelope  $r_* = r(\sigma = \pm\Delta\sigma_*)$  where  $r$  is the  
97 distance from the static stress source (e.g., mainshock rupture) and  $r_*$  the distance  $r$  at  
98 which there is a change of regime (quiescence/background at  $\sigma = -\Delta\sigma_*$  or  
99 background/activation at  $\sigma = \Delta\sigma_*$ ). The spatiotemporal rate of seismicity is then a  
100 mathematical expression defined by the density of events  $\delta$  times the volume  
101 characterized by  $r_*$  (see previous demonstrations in Mignan et al. (2007) and Mignan  
102 (2011; 2012; 2016a) where simple algebraic expressions were obtained).

103 In the case of aftershocks, we define the static stress field of the mainshock by

$$104 \quad \sigma(r) = -\Delta\sigma_0 \left[ \left( 1 - \frac{c^3}{(r+c)^3} \right)^{-1/2} - 1 \right] \quad (6)$$

105 with  $\Delta\sigma_0 < 0$  the mainshock stress drop,  $c$  the crack radius and  $r$  the distance from the  
106 crack. Eq (6) is a simplified representation of stress change from slip on a planar

107 surface in a homogeneous elastic medium. It takes into account both the square root  
 108 singularity at crack tip and the  $1/r^3$  falloff at higher distances (Dieterich, 1994; Fig.  
 109 1b). It should be noted that this radial static stress field does not represent the  
 110 geometric complexity of Coulomb stress fields (Fig. 2a). However we are here only  
 111 interested in the general behavior of aftershocks with Eq. (6) retaining the first-order  
 112 characteristics of this field (i.e., on-fault seismicity; Fig. 2b), which corresponds to the  
 113 case where the mainshock relieves most of the regional stresses and aftershocks occur  
 114 on optimally oriented faults. It is also in agreement with observations, most  
 115 aftershocks being located on and around the mainshock fault traces in Southern  
 116 California (Fig. 2c; see section “Observations & Model Fitting”). The occasional  
 117 cases where aftershocks occur off-fault (e.g., Ross et al., 2017) can be explained by  
 118 the mainshock not relieving all of the regional stress (King et al., 1994; Fig. 2d).

119 For  $r_* = r(\sigma = \Delta\sigma_*)$ , Eq. (6) yields the aftershock solid envelope of the form:

$$120 \quad r_*(c) = \left\{ \frac{1}{\left[1 - \left(1 - \frac{\Delta\sigma_*}{\Delta\sigma_0}\right)^{-2}\right]^{1/3}} - 1 \right\} c = Fc, \quad (7)$$

121 function of the crack radius  $c$  and of the ratio between background stress amplitude  
 122 range  $\Delta\sigma_*$  and stress drop  $\Delta\sigma_0$  (Fig. 1c). With  $\Delta\sigma_0$  independent of earthquake size  
 123 (Kanamori and Anderson, 1975; Abercrombie and Leary, 1993) and  $\Delta\sigma_*$  assumed  
 124 constant,  $r_*$  is directly proportional to  $c$  with proportionality constant, or stress factor,  
 125  $F$  (Eq. 7). Geometrical constraints due to the seismogenic layer width  $w_0$  then yield

$$126 \quad c(M) = \begin{cases} \left(\frac{S(M)}{\pi}\right)^{1/2} & , S(M) \leq \pi w_0^2 \\ w_0 & , S(M) > \pi w_0^2 \end{cases} \quad (8)$$

127 with  $S$  the rupture surface area defined by Eq. (4) and  $c$  becoming an effective crack  
 128 radius (Kanamori and Anderson, 1975; Fig. 1d). Note that the factor of 2 (i.e., using

129  $w_0$  instead of  $w_0/2$ ) comes from the free surface effect (e.g., Kanamori and Anderson,  
 130 1975; Shaw and Scholz, 2001).

131 The aftershock productivity  $K(M)$  is then the activation density  $\delta_+$  times the  
 132 volume  $V_*(M)$  of the aftershock solid. For the case in which the mainshock relieves  
 133 most of the regional stress, stresses are increased all around the rupture (King et al.,  
 134 1994), which is topologically identical to stresses increasing radially from the rupture  
 135 plane (Fig. 2a-b). It follows that the aftershock solid can be represented by a volume  
 136 of contour  $r_*(M)$  from the rupture plane geometric primitive, i.e., a disk or a  
 137 rectangle, for small and large mainshocks, respectively. This is illustrated in Figure  
 138 3a-b and can be generalized by

$$139 \quad V_*(M) = 2r_*(M)S(M) + \frac{\pi}{2}r_*^2(M)d \quad (9)$$

140 where  $d$  is the distance travelled around the geometric primitive by the geometric  
 141 centroid of the semi-circle of radius  $r_*(M)$  (i.e., Pappus's Centroid Theorem), or

$$142 \quad d = \begin{cases} 2\pi \left( c(M) + \frac{4}{3\pi} r_*(M) \right) & , c(M) + r_*(M) \leq \frac{w_0}{2} \\ 2w_0 & , c(M) + r_*(M) > \frac{w_0}{2} \end{cases} \quad (10)$$

143 For the disk, the volume (Eq. 9) corresponds to the sum of a cylinder of radius  $c(M)$   
 144 and height  $2r_*(M)$  (first term) and of half a torus of major radius  $c(M)$  and minus  
 145 radius  $r_*(M)$  (second term). For the rectangle, the volume is the sum of a cuboid of  
 146 length  $l(M)$  (i.e., rupture length), width  $w_0$  and height  $2r_*(M)$  (first term) and of a  
 147 cylinder of radius  $r_*(M)$  and height  $w_0$  (second term; see red and orange volumes,  
 148 respectively, in Figure 3a-c). Finally inserting Eqs. (7), (8) and (10) into (9), we  
 149 obtain

$$150 \quad K(M) = \delta_+ \begin{cases} \left[ \frac{2F}{\sqrt{\pi}} + F^2 \sqrt{\pi} \left( 1 + \frac{4}{3\pi} F \right) \right] S^{3/2}(M) & , S(M) \leq \left( \frac{w_0 \sqrt{\pi}}{2(1+F)} \right)^2 \\ \frac{2F}{\sqrt{\pi}} S^{3/2}(M) + F^2 w_0 S(M) & \left( \frac{w_0 \sqrt{\pi}}{2(1+F)} \right)^2 < S(M) \leq \pi w_0^2 \\ 2F w_0 S(M) + \pi F^2 w_0^3 & , S(M) > \pi w_0^2 \end{cases}$$

151 (11)

152 which is represented in Figure 3d. Considering the two main regimes only (small  
153 versus large mainshocks) and inserting Eq. (4) into (11), we get

$$154 \quad K(M) = \delta_+ \begin{cases} \left[ \frac{2F}{\sqrt{\pi}} + F^2 \sqrt{\pi} \left( 1 + \frac{4}{3\pi} F \right) \right] \exp \left[ \frac{3 \ln(10)}{2} (M - 4) \right] & , \text{small } M \\ 2F w_0 \exp[\ln(10)(M - 4)] + \pi F^2 w_0^3 & , \text{large } M \end{cases} \quad (12)$$

155 which is a closed-form expression of the same form as the original Utsu productivity  
156 law (Eq. 1). Note that  $K$  and  $\delta_+$  are both, implicitly, function of the selected minimum  
157 aftershock magnitude threshold  $m_0$ .

158 Here, we predict that the  $\alpha$ -value decreases from  $3 \ln(10)/2 \approx 3.45$  to  $\ln(10) \approx$   
159  $2.30$  when switching regime from small to large mainshocks (or from 1.5 to 1 in base-  
160 10 logarithmic scale). It should be noted that Hainzl et al. (2010) observed the same  
161 break in scaling in static stress transfer simulations, which corroborates our analytical  
162 findings. Hainzl et al. (2010) simulated aftershocks using the clock-change model  
163 where events were advanced in time by the static stress change produced by a  
164 mainshock in a three-dimensional medium. They explained the scaling break  
165 observed in simulation as a transition from 3D to 2D scaling regime when the  
166 mainshock rupture dimension approached  $w_0$ , which is compatible with the present  
167 demonstration. For large  $M$ , the scaling is fundamentally the same as in Eq. (4). Since  
168 that relation also explains the slope of the Gutenberg-Richter law (see physical  
169 explanation given by Kanamori and Anderson, 1975), it follows that  $\alpha \equiv \beta$ , which is  
170 also in agreement with the original formulation of Utsu (1970a; b; Eq. 3).

171

172 *2.2. Testing of the SSP on the aftershock spatial distribution*

173 The SSP predicts a step-like behavior of the aftershock spatial density for an  
174 idealized smooth static stress field (Fig. 4a-b), which is in disagreement with real  
175 aftershock observations. A number of studies have shown that the spatial linear  
176 density distribution of aftershocks  $\rho$  is well represented by a power-law, expressed as  
177 
$$\rho(r) \propto r^{-q} \quad (13)$$
  
178 with  $r$  the distance from the mainshock and  $q$  the power-law exponent. This parameter  
179 ranges over  $1.3 \leq q \leq 2.5$  (Felzer and Brodsky, 2006; Lipiello et al., 2009; Marsan and  
180 Lengliné, 2010; Richards-Dinger et al., 2010; Shearer, 2012; Gu et al., 2013;  
181 Moradpour et al., 2014; van der Elst and Shaw, 2015). Although Felzer and Brodsky  
182 (2004) suggested a dynamic stress origin for aftershocks, their results were later on  
183 questioned by Richards-Dinger et al. (2010). Most of the studies cited above suggest  
184 that the  $q$ -value is explained from a static stress process. As for the examples of  
185 aftershocks shown to be dynamically triggered (e.g., Fan and Shearer, 2016), they are  
186 too few to alter the aftershock productivity law and too remote to be consistently  
187 defined as aftershocks in cluster methods.

188 In a more realistic setting, the static stress field must be heterogeneous (due to  
189 the occurrence of previous events and other potential stress perturbations). We  
190 therefore simulate the static stress field by adding a uniform random component  
191 bounded over  $\pm\Delta\sigma_*$  following Mignan (2011) (see also King and Bowman, 2003).  
192 Note that any deviation above  $\Delta\sigma_*$  would be flattened to  $\Delta\sigma_*$  over time by temporal  
193 diffusion (so-called “historical ghost static stress field” in Mignan, 2016a). Figure 4c  
194 shows the resulting stress field and Figure 4d the predicted aftershock spatial density.  
195 Adding uniform noise blurs the contour of the aftershock solid, switching the  
196 aftershock spatial density from a step function (Fig. 4b) to a power-law (Fig. 4d). We

197 fit Eq. (13) to the simulated data using the Maximum Likelihood Estimation (MLE)  
198 method with  $r_{min} = r_*$  (Clauset et al., 2009) and find  $q = 1.96 \pm 0.01$ , in agreement with  
199 the aftershock literature. This result alone is however insufficient to prove the validity  
200 of the SSP.

201

### 202 **3. Observations & Model Fitting**

#### 203 *3.1. Data*

204 We consider the case of Southern California and extract aftershock sequences  
205 from the relocated earthquake catalog of Hauksson et al. (2012) defined over the  
206 period 1981-2011, using the nearest-neighbor method (Zaliapin et al., 2008; used with  
207 its standard parameters originally calibrated for Southern California, considering only  
208 the first aftershock generation). Only events with magnitudes greater than  $m_0 = 2.0$  are  
209 considered (a conservative estimate following results of Tormann et al. (2014);  
210 saturation effects immediately after the mainshock are negligible when considering  
211 entire aftershock sequences; Helmstetter et al., 2005).

212

#### 213 *3.2. Aftershock spatial density distribution*

214 Figure 5a represents the spatial linear density distribution of aftershocks  $\rho(r)$   
215 for the four largest strike-slip mainshocks in Southern California: 1987  $M=6.6$   
216 Superstition Hills, 1992  $M=7.3$  Landers, 1999  $M=7.1$  Hector Mine, and 2010  $M=7.2$   
217 El Mayor. The distance between mainshock and aftershocks is calculated as  
218  $r = \sqrt{(x - x_0)^2 + (y - y_0)^2}$  with  $(x, y)$  the aftershock coordinates and  $(x_0, y_0)$  the  
219 coordinates of the nearest point to the mainshock fault rupture (as depicted in Figure  
220 2c). The dashed black lines shown in Figure 5a are visual guides to  $q = 1.96$ , showing  
221 that the SSP is compatible with real aftershock observations.

222 Comparing Figure 5a to Figure 4d suggests that  $r_*$  can be roughly estimated  
 223 from the spatial linear density plot, being the maximum distance  $r$  at which the  
 224 plateau ends, here leading to  $r_* \approx 1$  km. This parameter is constant for different large  
 225  $M$  values since both  $w_0$  and  $\Delta\sigma_0$  are constant while  $\Delta\sigma_*$  is also *a priori* a constant. We  
 226 can then estimate the ratio  $\Delta\sigma_*/\Delta\sigma_0$  from Eq. (7). However the result is ambiguous  
 227 due to uncertainties on the width  $w_0$ . For  $w_0 = \{5, 10, 15\}$  km, we get  $\Delta\sigma_*/\Delta\sigma_0 = \{-$   
 228  $0.54, -1.01, -1.38\}$ .

229 As for the plateau value  $\rho(r < r_*)$ , it provides an estimate of the aftershock  
 230 activation density  $\delta_+$  with

$$231 \quad \delta_+ = \frac{\rho(M, r < r_*)}{\exp[\ln(10)(M-4)]} \quad (14)$$

232 a volumetric density, i.e. the linear density  $\rho$  normalized by the mainshock rupture  
 233 area (Eq. 4). Due to the fluctuations in  $\rho(r < r_*)$ ,  $\delta_+$  will be estimated from the  
 234 productivity law instead (see section 3.3) and  $\rho(r < r_*)$  then estimated from Eq. (14)  
 235 (horizontal dashed colored lines), as detailed below.

236 It should be noted that we consider only the first-generation aftershocks to  
 237 avoid  $\rho$  heterogeneities from secondary aftershock clusters occurring off-fault. An  
 238 example of such heterogeneity/anisotropy is illustrated by the Landers-Big Bear case  
 239 (Fig. 2c; dotted colored curve on Fig. 5a). Those cases are not systematic and  
 240 therefore not considered in the aftershock productivity law. However they are also  
 241 due to static stress changes (e.g., King et al., 1994) with the anisotropic effects  
 242 explainable by Solid Seismicity through the concept of “historical ghost static stress  
 243 field” (Mignan, 2016a).

244

245 *3.3. Aftershock productivity law*

246 The observed number  $n$  of aftershocks of magnitude  $m \geq m_0$  produced by a  
 247 mainshock of magnitude  $M$  (for a total of  $N$  mainshocks) in Southern California is  
 248 shown in Figures 5b (for large  $M \geq 6$ ) and 6a (for the full range  $M \geq m_0$ ). We fit Eq.  
 249 (1) to the data using the MLE method with the log-likelihood function

$$250 \quad LL(\theta; X = \{n_i; i = 1, \dots, N\}) = \sum_{i=1}^N [n_i \ln[K_i(\theta)] - K_i(\theta) - \ln(n_i!)] \quad (15)$$

251 for a Poisson process, representing the stochasticity of the count  $K$  of aftershocks  
 252 produced by a mainshock at any given time. Inserting Eq. (1) in Eq. (15) yields

$$253 \quad LL(\theta = \{K_0, \alpha\}; X) = \ln(K_0) \sum_{i=1}^N n_i + \alpha \sum_{i=1}^N [n_i (M_i - m_0)] - K_0 \sum_{i=1}^N \exp[\alpha (M_i -$$

$$254 \quad m_0)] - \sum_{i=1}^N \ln(n_i!) \quad (16)$$

255 (note that the last term can be set to 0 during  $LL$  maximization). For Southern  
 256 California, we obtain  $\alpha_{\text{MLE}} = 2.32$  (1.01 in  $\log_{10}$  scale) and  $K_0 = 0.025$  when  
 257 considering large  $M \geq 6$  mainshocks only to avoid the issues of scaling break and data  
 258 dispersion at lower magnitudes. This result, represented by the black solid line on  
 259 Figure 5b, is in agreement with previous studies in the same region (e.g., Helmstetter,  
 260 2003; Helmstetter et al., 2005; Zaliapin and Ben-Zion, 2013; Seif et al., 2017) and  
 261 with  $\alpha = \ln(10) \approx 2.30$  predicted for large mainshocks in Solid Seismicity (Eq. 12).  
 262 Moreover we find a bulk  $\beta_{\text{MLE}} = 2.34$  (1.02 in  $\log_{10}$  scale) (Aki, 1965), in agreement  
 263 with  $\alpha \equiv \beta$ .

264 Let us now rewrite the Solid Seismicity aftershock productivity law (Eq. 12)  
 265 by only considering the large  $M$  case and injecting  $r_* = Fw_0$  (by combining Eqs. 7-8).  
 266 We get

$$267 \quad K(M > M_{\text{break}}) = \delta_+ \{2r_* \exp[\ln(10)(M - 4)] + \pi r_*^2 w_0\} \quad (17)$$

268 The role of  $w_0$  is illustrated in Figure 5b for different values (dashed and dotted  
 269 curves) and shown to be insignificant for large  $M$  values. Therefore Eq. (17) can be  
 270 approximated to

271  $K(M > M_{break}) \approx 2\delta_+ r_* \exp[\ln(10)(M - 4)]$  (18)

272 By analogy with Eq. (1), we get

273  $\delta_+ = \frac{K_0 \exp[\ln(10)(4 - m_0)]}{2r_*}$  (19)

274 With  $r_* \approx 1$  km estimated from  $\rho(r)$  (section 3.2) and  $K_0 = 0.025$ , we obtain  $\delta_+ = 1.23$   
 275 events/km<sup>3</sup> for  $m_0 = 2$ . We then get back the plateau  $\rho(r < r_*)$  for different  $M$  values  
 276 from Eq. (14), as shown in Figure 5a (horizontal dashed colored lines). Although  
 277 based on limited data, this result suggests that the activation parameter  $\delta_+$  is constant  
 278 (at least for large  $M$ ) in Southern California. Note that if  $\rho(r < r_*)$  was well  
 279 constrained, it could have been estimated jointly with  $r_*$  from Figure 5a to predict the  
 280 aftershock productivity law of Figure 5b without further fitting required (hence  
 281 removing  $K_0$  from the equation,  $K_0$  having no physical meaning in Solid Seismicity).

282

#### 283 4. Role of aftershock selection on productivity scaling-break

284 We tested the following piecewise model to identify any break in scaling at  
 285 smaller  $M$ , as predicted by Eq. (12):

286 
$$K(M) = \begin{cases} K_0 \frac{\exp[\ln(10)(M_{break} - m_0)]}{\exp[\frac{3}{2}\ln(10)(M_{break} - m_0)]} \exp\left[\frac{3}{2}\ln(10)(M - m_0)\right] & , M \leq M_{break} \\ K_0 \exp[\ln(10)(M - m_0)] & , M > M_{break} \end{cases}$$

287 (20)

288 but with the best MLE result obtained for  $M_{break} = m_0$ , suggesting no break in scaling  
 289 in the aftershock productivity data, as observed in Figure 6a. Final parameter  
 290 estimates are  $\alpha_{MLE} = 1.95$  (0.85 in log<sub>10</sub> scale) and  $K_0 = 0.141$  for the full mainshock  
 291 magnitude range  $M \geq m_0$  (dotted line), subject to high scattering at low  $M$  values.

292 We now identify whether the lack of break in scaling in aftershock  
 293 productivity observed in earthquake catalogues could be an artefact related to the

294 aftershock selection method. We run Epidemic-Type Aftershock Sequence (ETAS)  
 295 simulations (Ogata, 1988; Ogata and Zhuang, 2006), with the seismicity rate

$$296 \begin{cases} \lambda(t, x, y) = \mu(t, x, y) + \sum_{i:t_j < t} K(M_i) f(t - t_i) g(x - x_i, y - y_i | M_i) \\ f(t) = c^{p-1} (p - 1) (t + c)^{-p} \\ g(x, y | M) = \frac{1}{\pi} (d e^{\gamma(M-m_0)})^{q-1} (x^2 + y^2 + d e^{\gamma(M-m_0)})^{-q} (q - 1) \end{cases} \quad (21)$$

297 Aftershock sequences are defined by power laws, both in time and space (for an  
 298 alternative temporal function, see Mignan (2015; 2016b); the spatial power-law  
 299 distribution is in agreement with Solid Seismicity in the case of a heterogeneous static  
 300 stress field – see section 2.2).  $\mu$  is the Southern California background seismicity, as  
 301 defined by the nearest-neighbor method (with same  $t, x, y$  and  $m$ ). We fix the ETAS  
 302 parameters to  $\theta = \{c = 0.011 \text{ day}, p = 1.08, d = 0.0019 \text{ km}^2, q = 1.47, \gamma = 2.01, \beta =$   
 303  $2.29, K_0 = 0.08\}$ , following the fitting results of Seif et al. (2017) for the Southern  
 304 California relocated catalog and  $m_0 = 2$  (see their Table 1). However, we define the  
 305 productivity function  $K(M)$  from Eq. (20) with  $M_{break} = 5$ . Examples of ETAS  
 306 simulations are shown in Figure 6b for comparison with the observed Southern  
 307 California time series. Figure 6c allows us to verify that the simulated aftershock  
 308 productivity is kinked at  $M_{break}$ , as defined by Eq. (20).

309 We then select aftershocks from the ETAS simulations with the nearest-  
 310 neighbor method. Figure 4d represents the estimated aftershock productivity, which  
 311 has lost the break in scaling originally implemented in the simulations (with an  
 312 underestimated  $\alpha_{MLE} = 2.07$  as observed in the real case for  $M \geq m_0$ ). Note that a  
 313 similar result is obtained when using a windowing method (Gardner and Knopoff,  
 314 1974). This demonstrates that the theoretical break in scaling predicted in the  
 315 aftershock productivity law can be lost in observations due to an aftershock selection  
 316 bias, all declustering techniques assuming continuity over the entire magnitude range.  
 317 While such a bias is possible, it yet does not prove that the break in scaling exists. The

318 fact that a similar break in scaling was obtained in independent Coulomb stress  
319 simulations (Hainzl et al., 2010) however provides high confidence in our results.

320 One other possible explanation for lack of scaling break is that our  
321 demonstration assumes moment magnitudes while the Southern California catalogue  
322 is in local magnitudes. Deichmann (2017) demonstrated that while  $M_L \propto M_w$  at large  
323  $M$ ,  $M_L \propto 1.5M_w$  at smaller  $M$  values. This could in theory cancel the kink in real data.  
324 However the scaling break predicted by Deichmann (2017) occurs at several  
325 magnitude units below the geometric scaling break expected by Solid Seismicity,  
326 invalidating this second option for mid-range magnitudes  $M$ .

327

## 328 **5. Conclusions**

329 In the present study, a closed-form expression defined from geometric and  
330 static stress parameters was proposed (Eq. 12) to describe the empirical Utsu  
331 aftershock productivity law (Eq. 1). This demonstration is similar to the previous ones  
332 made by the author to explain precursory accelerating seismicity and induced  
333 seismicity (Mignan, 2012; 2016b). In all these demonstrations, the main physical  
334 parameters remain the same, i.e. the activation density  $\delta_+$  (also  $\delta_-$  and  $\delta_0$ ), the  
335 background stress amplitude range  $\Delta\sigma_*$ , and the solid envelope  $r_*$  which describes the  
336 geometry of the “seismicity solid” (Fig. 3a-b). Further studies will be needed to  
337 evaluate whether the  $\delta_+$  and  $\Delta\sigma_*$  parameters are universal or region-specific and if the  
338 same values apply to different types of seismicity at a same location.

339 Although the Solid Seismicity Postulate (SSP) (Eq. 5) remains to be proven, it  
340 is so far a rather convenient and pragmatic assumption to determine the physical  
341 parameters that play a first-order role in the behavior of seismicity. The similarity of  
342 the SSP-simulated and observed values of the power-law exponent  $q$  of the aftershock

343 spatial density distribution shows that the SSP is consistent with large aftershock  
344 observations once uniform noise is added to the stress field (Figs. 4d-5a). The impact  
345 of other types of noise on  $q$  has yet to be investigated. The SSP is also complementary  
346 to the more common simulations of static stress loading (King and Bowman, 2003)  
347 and static stress triggering (Hainzl et al., 2010).

348 Analytic geometry, providing both a visual representation and an analytical  
349 expression of the problem at hand (Fig. 3), represents a new approach to try to better  
350 understand the behavior of seismicity. Its current limitation in the case of aftershock  
351 analysis consists in assuming that the static stress field is radial and described by Eq.  
352 (6) (e.g., Dieterich, 1994), which is likely only valid for mainshocks relieving most of  
353 the regional stresses and with aftershocks occurring on optimally oriented faults (King  
354 et al., 1994). More complex, second-order, stress behaviors might explain part of the  
355 scattering observed around Eq. (1) (Fig. 6a), such as overpressure due to trapped high-  
356 pressure gas for example (Miller et al., 2004 – see also Mignan (2016a) for an  
357 overpressure field due to fluid injection). Other  $\sigma(r)$  formulations could be tested in  
358 the future, the only constraint on generating so-called seismicity solids being the use  
359 of the postulated static stress step function of Eq. (5) (i.e., the Solid Seismicity  
360 Postulate, SSP).

361 Finally, the disappearance of the predicted scaling break in the aftershock  
362 productivity law once declustering is applied (Fig. 6) indicates that more work is  
363 required in that domain. Only a declustering technique that does not dictate a constant  
364 scaling at all  $M$  will be able to identify rather a scaling break really exists or not.

 511 relieves all of the regional stresses  $\sigma_r = 10$  bar, with  $\Delta\sigma_0 \approx -Gs/L \approx -10$  bar ( $G =$   
 512  $3.3 \cdot 10^5$  bar the shear modulus,  $s = 0.6$  m the slip,  $L = 20$  km the fault length, and  $w =$   
 513  $10$  km the fault width); (b) Radial static stress field computed from Eq. (6) with  $\Delta\sigma_0 =$   
 514  $-10$  bar and  $c = \sqrt{(Lw)/\pi}$  for consistency with (a); (c) Aftershock distribution of the  
 515 largest strike-slip events in the Southern California relocated catalog, identified here

516 as all events occurring within one day of the mainshock (see Data section 3.1); (d)  
 517 Right-lateral Coulomb stress field for optimally oriented faults, where the mainshock  
 518 relieves only a fraction of the regional stresses  $\sigma_r = 100$  bar with  $\Delta\sigma_0 = -10$  bar (same  
 519 rupture as in (a)) – The black contour represents 1 bar in (a), (b) and (d), and a 10 km  
 520 distance from rupture in (c). Coulomb stress fields of (a) and (d) were computed using  
 521 the Coulomb 3 software (Lin and Stein, 2004; Toda et al., 2005).  
 522

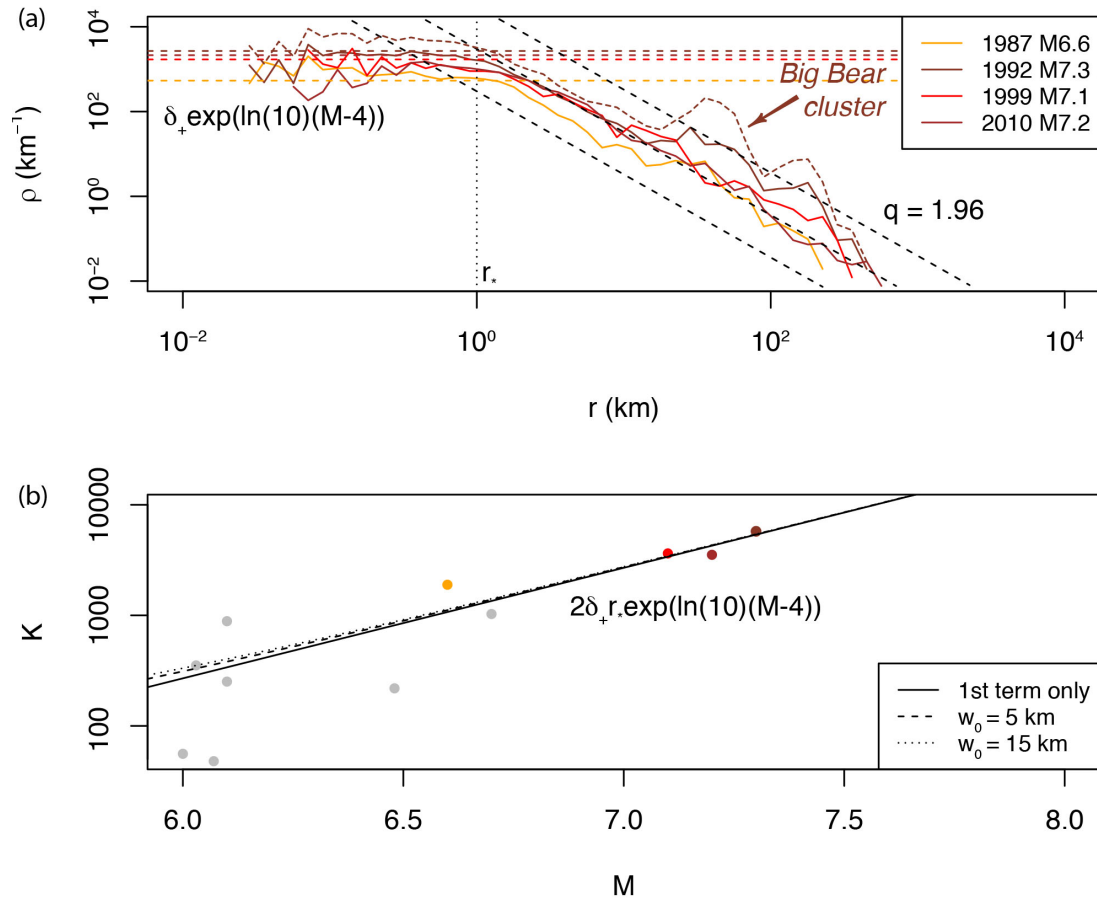

523  
 524 **Figure 3.** Geometric origin of the aftershock productivity law: (a) Sketch of the  
 525 aftershock solid for a small mainshock rupture represented by a disk; (b) Sketch of the  
 526 aftershock solid for a large mainshock rupture represented by a rectangle; (c) Relative  
 527 role of the two terms of Eq. (9), here with  $w_0 = 10$  km and  $\frac{\Delta\sigma_*}{\Delta\sigma_0} = -0.1$  (to first estimate  
 528  $c$  and  $r_*$  from Eqs. 8 and 7, respectively); (d) Aftershock productivity law (normalized

529 by  $\delta_+$ ) predicted by Solid Seismicity (Eq. 11). This relationship is of the same form as  
 530 the Utsu productivity law (Eq. 1) for large  $M$  (see text for an explanation of the lack  
 531 of break in scaling in Eq. 1 for small  $M$ ). Dotted vertical lines represent  $M$  for  
 532  $c(M) + r_*(M) = \frac{w_0}{2}$  and  $S(M) = \pi w_0^2$ , respectively.  
 533

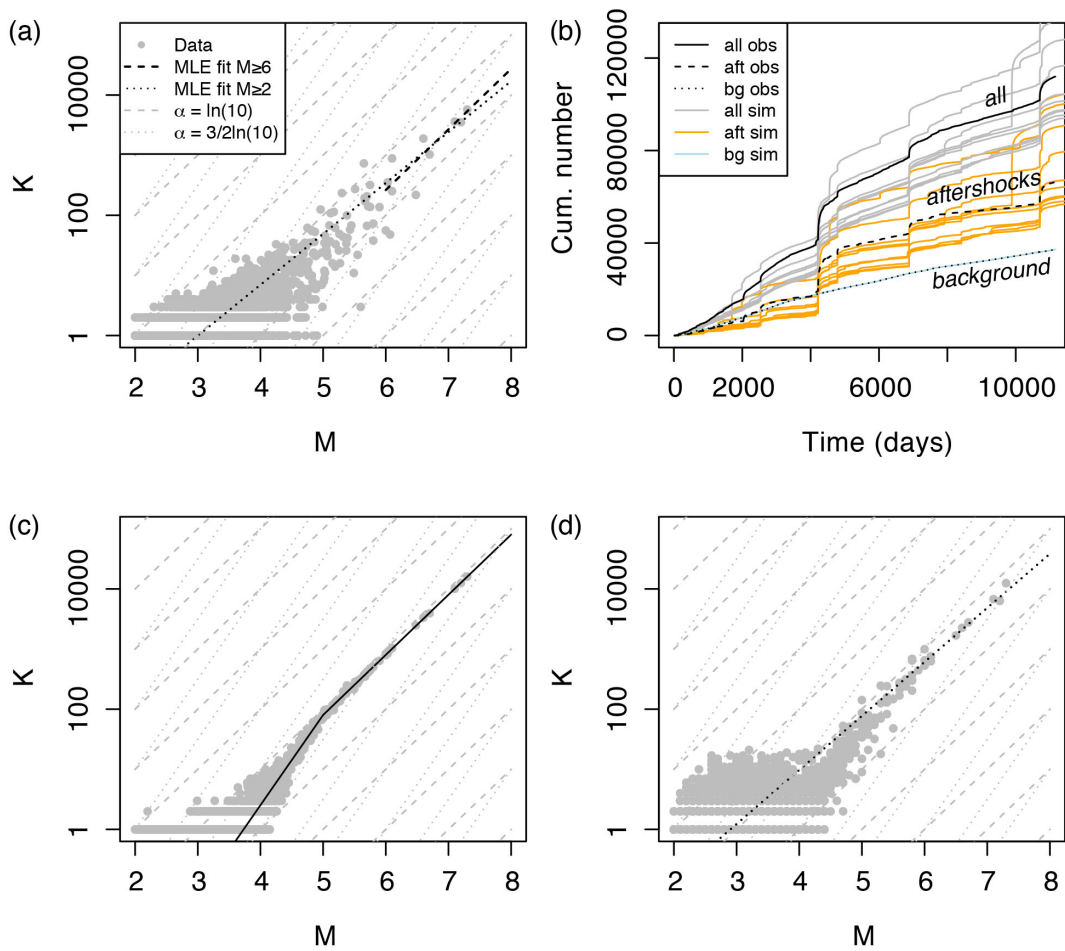

534  
 535 **Figure 4.** Spatial distribution of aftershocks following the SSP. (a) Smooth static  
 536 stress field as a function of distance  $r$  from the mainshock, with  $\Delta\sigma_0 = -10$  bar and  $c =$   
 537 10 km (Eq. 6); (b) Step-like aftershock spatial linear density  $\rho(r)$  with  $\delta_+ = 1000$   
 538 events per km,  $\delta_0 = 1$  event per km and  $\Delta\sigma_* = -0.3\Delta\sigma_0$  (*ad-hoc* ratio yielding  $r_* = 3.5$   
 539 km; Eq. (7) – event distances sampled from the  $\delta(r)$  distribution, repeated 100 times).  
 540 Such distribution is not observed in Nature; (c) Same as (a) but with random uniform

541 noise representative of spatial heterogeneities added to the regional stress field; (d)  
 542 Power-law-like aftershock spatial linear density  $\rho(r)$  with power exponent MLE  
 543 estimate  $q = 1.96$ , representative of real aftershock observations (see Fig. 5a), due to  
 544 the addition of uniform noise to the static stress field.  
 545

546  
 547 **Figure 5.** Estimating the Solid Seismicity parameters from the spatial distribution of  
 548 aftershocks: (a) Spatial linear density distribution  $\rho(r)$  of aftershocks for the four  
 549 largest strike-slip mainshocks in Southern California (with first-generation  
 550 aftershocks only; the density distribution comprising all aftershocks generated by the  
 551 Landers mainshock is represented by the dotted curve to illustrate the type of spatial  
 552 heterogeneity, such as the Big Bear cluster, not considered in the present study – see  
 553 also Fig. 2c). The Solid Seismicity parameters  $r_* = 1$  km and  $\delta_+(m_0 = 2) = 1.23$

554 events/km<sup>3</sup> can be retrieved from the observed plateau  $\rho(r < r_*)$ , in agreement with the  
 555 SSP (see Fig. 4d). Note that the spatial power-law decay at high  $r$  is similar to the one  
 556 expected by the SSP in the case of a static stress field with additive uniform noise  
 557 (expected  $q = 1.96$  represented by the dashed black lines); (b) Aftershock productivity  
 558  $K$  for  $M > 6$ . The curves represent the productivity law as defined by Solid Seismicity  
 559 (Eq. 17) for different  $w_0$  values (first term only corresponds to  $w_0 = 0$ ; Eq. 18).  
 560

561  
 562 **Figure 6.** Aftershock productivity defined as the number of aftershocks  $K(m_0 = 2)$  per  
 563 mainshock of magnitude  $M$ : (a) Observed aftershock productivity in Southern  
 564 California with aftershocks selected using the nearest-neighbor method; (b)  
 565 Seismicity time series with distinction made between background events and

566 aftershocks, observed (“obs”, in black) and ETAS-simulated (“sim”, colored); (c)  
567 True simulated aftershock productivity with kink, defined from Eq. (20); (d)  
568 Retrieved simulated aftershock productivity with aftershocks selected using the  
569 nearest-neighbor method - Data points in (a), (c) and (d) are represented by grey dots;  
570 the model MLE fits are represented by the dashed and dotted black lines for  $M \geq 6$   
571 and  $M \geq m_0$ , respectively; dashed and dotted grey lines are visual guides to  $\alpha =$   
572  $3/2\ln(10)$  and  $\ln(10)$ , respectively.  
573
